S. stercoralis L3i (infective larvae) are shown to find and infect hosts using specific host-emitted olfactory, thermosensory and gustatory cues. The most attractive component is urocanic acid, a histidine metabolite particularly abundant in mammalian skin, whose activity may be inhibited by metal ions (Safer et al., 2007). A variety of metalloproteinases play important role in tissue penetration, immune evasion, disruption of host blood coagulation cascades (Rajamanickam et al., 2016). Hystolytic metalloprotease secreted by L3 larvae catalyze the degradation of dermal extracellular matrix facilitating the rapid migration (McKerrow et al., 1990). An astacin-like metalloproteinase, strongylastacin, is demonstrated to elicit specific IgE antibody in *S. stercoralis* infected humans (Varatharajulu et al., 2011). Recently, significant advances in studies of host seeking have been made possible by the application of CRISPR-associated protein 9 (CRISPR/Cas9) technology to molecular components of sensory neuronal signaling; the knockout of Ss-TAX-4 gene, highly conserved in sensory neurons of nematode, was shown to affect the normal thermotaxis in *S. stercoralis* (Bryant et al., 2018). The host innate and adaptive immune response play a critical role in the maintenance of chronic strongyloidosis and the prevention of hyperinfection syndrome and dissemination (Weatherhead and Mejia, 2014). During primary infection, the recruitment of neutrophils, eosinophils and macrophages to the parasite microenvironment result in release of myeloperoxidase (MPO) from neutrophils and major basic protein (MBP) from eosinophils, which are toxic to larvae, and activation of complement component C3b to kill the pathogen (Bonne-Année et al., 2011). The transition from the innate to the adaptive response requires the capacity of eosinophils to act as APC (antigen presenting cell), presenting parasite antigens to T cells, resulting in the activation of Th-2 response, which is protective against helminth infections. Th-2 cells produce cytokines including IL-4 and IL-5. IL-4 activates B lymphocytes to class-switch for production of IgE and IgG4 antibodies, whereas IL-5 is essential for differentiation, proliferation of eosinophils.

Thymic stromal lymphopoietin (TSLP) has been considered important for initiating innate and adaptive responses (Ziegler and Artis, 2010). TSLP is one of the tissue factors mainly expressed by epithelial cells at barrier surface. After helminth infection and disruption of colonic epithelium caused by penetration and migration of the *Strongyloides* larvae through the dermis, TSLP acts promoting and regulating the Th-2 cytokine response, dendritic cells and the effector functions of CD4 + Th-2 cells, basophils and granulocyte populations. TSLP was shown to promote protective immunity to *Trichuris muris*, *Nippostrongylus brasiliensis*, *Heligmosomoides polygyrus*, and *Schistosoma mansoni* in mice, but the role in protective immunity to *S. stercoralis* still remains uncertain (Ziegler and Artis, 2010). Further investigations have demonstrated that TSLP play an important parasite specific role in the worm expulsion during *T. muris* and *T. spiralis* infection, whereas its deficiency does not impair type 2 cytokine response following infection with *S. mansoni* (Inclan-Rico and Siracusa, 2018).

Fig. 1 The life cycle of *S. stercoralis*: parasitic and free-living cycle. From <https://www.cdc.gov/dpdx/strongyloidiasis/index.html>.

The molecular and cellular mechanism remain topics of considerable debate and controversy. Most of the evidence suggests that epithelial cells make important contributions toward Th-2 differentiation (Artis et al., 2008; Zhu et al., 2010).

Trefoil factor 2 (TFF2), produced by epithelial cells, has a critical role during larval migration through the lungs (Wills-Karp et al., 2012). In the lungs, TFF2 triggers the release of IL-33, a type 2 inflammation regulator, from lung epithelia within 24 h after infection. IL-33 activates innate cells including lymphoid cells, eosinophils and DCs. The DC stimulation of TH2 cells induces an amplified production of IL-4, IL-5 and IL-13, which drive alternatively the activation of macrophages involved in the attack of the lung migrating larvae (Maizels et al., 2012), adding to the eosinophils contribution. In mice infected with *Strongyloides venezuelensis*, IL-33 production stimulates IL-5 release, resulting in eosinophilia, contributing to worm expulsion (Yasuda et al., 2012).

Basophils are also functional for the host's protective Th2 response. Their number expand in blood and mesenteric lymph for the control of early intestinal parasite expulsion, during intestinal infection with *Strongyloides ratti* in mice. By contrast, in basophils-deficient mice, the absence of these cells as intestinal effectors, clearly impairs the efficient control of parasite burden (Reitz et al., 2018). Although basophils and mucosal mast cells have overlapping functions in contributing to the early intestinal immunity, the expulsion of the *S. ratti* nematodes has been proven to be selectively dependent on mast cells presence, alone or in synergy with basophils (Reitz et al., 2017).

Granulocytes are crucial for the host's defense against migrating larvae. The histological examination of skin, lungs and small intestine of mice infected with *S. ratti* revealed an inflammatory reaction due to neutrophils and eosinophils surrounding larvae 12 h after infection, whereas mononuclear cells were around the worms more than 24 h later (Dawkins et al., 1981).

Toll-like receptors (TLRs) are involved in recognition of pathogens via pathogen-associated molecular patterns (PAMPs) and in development of protective immunity against larval *S. stercoralis* in murine model. Interestingly, TLR4 is capable to induce the Th2-mediated allergic asthma in mice and DC2 phenotype acquisition by dendritic cells in case of helminth infection (Kerepesi et al., 2007). By means of an innovative method based on diffusion chambers containing L3 larvae and implanted in naïve mice,

TLR4 has been shown to be required for activating neutrophils in mediating parasites killing during the adaptive immune response. Neutrophils require both MPO and TLR4 to kill the larvae of *S. stercoralis* in the adaptive immune response (O'Connell et al., 2011). Animal in vitro models are essential for maintaining *Strongyloides* spp. in the laboratory and clarifying the interactions between adult worms and host immune response (Korenaga and Bruschi, 2014). The Mongolian gerbil was the first animal model of uncomplicated and hyperinfective *S. stercoralis* infection studied by Nolan et al. (1993) and a significant amelioration was obtained by Charuchaibovorn et al. (2019) as regards the potential applicability of gerbils infected with a human isolate of *S. stercoralis* as a good model for further immunological studies.

Helminth infections are highly prevalent in many low income countries where autoimmune disease are uncommon. For example, an inverse relation between autoimmune liver disease and *S. stercoralis* infection is the result of a disequilibrium of Th1 and Th2 cells, which are reciprocally cross-inhibitory and play a crucial role in downregulation of autoimmune processes. The pathogenesis of autoimmune liver diseases is modulated by *S. stercoralis* infection through Th1–Th2 cross-inhibitory process and/or induction of CD4 + regulatory T cell, which produce IL-10 and transforming growth factor- β (Aoyama et al., 2007).

Interestingly, in patients co-infected with Human T-lymphotropic virus 1 (HTLV-1) and *S. stercoralis*, the immunological shift to a Th-1 dominated immune response, induces a Th2 response blockade and leads to increased susceptibility to helminth infection with significantly lower eosinophil counts and serum IgE levels (Hirata et al., 2006). When *S. stercoralis* is present alone, Th-2 response induces IL-4 increase, which primes the B cells switching and the IgE production. Conversely, in case of co-infection with HTLV-1, an increased production of IFN γ , typical of a Th-1 response, occurs (Iriemenam et al., 2010). However, other mechanisms seem to be involved. Several studies have shown an association between ϵ chain expression and T-reg cells, which may contribute to the pathogenic mechanisms of HTLV-1 coinfection. An additional observation was done by Malpica et al. (2019), who studied the role of T-regs on the intestinal immune response, demonstrating the increased CD3 +, CD8 + and T-reg cell activities in duodenal biopsies of co-infected patients compared non-specific duodenitis or normal patients.

Clinical manifestations

Strongyloidosis has variable clinical pictures ranging from asymptomatic or mild (more frequent) to hyperinfection, or disseminated infection (Norsarwany et al., 2012). The initial signs of acute strongyloidosis may give a characteristic cutaneous reaction at the skin penetration site, commonly at the foot level, from which an urticarial tract with severe pruritus starts, lasting for several days. Cough and tracheal irritation are associated to the larvae migration through the lungs. Abdominal cramping and bloating, watery diarrhea are due to the lodging and maturation into adult of larvae at the host intestinal level (Keiser and Nutman, 2004). Chronic infections with *S. stercoralis* are sustained by a relatively low and stable number of adult worms; a well-regulated autoinfection, generally asymptomatic, either can lead to cutaneous, gastrointestinal or pulmonary symptoms. Skin involvement is characterized by a migratory, *larva currens* serpiginous maculopapular or urticarial rash along the buttocks, perineum and thighs due to repeated auto-infection (CDC, DPDx homepage). Gastrointestinal symptoms include diarrhea, abdominal discomfort, nausea and anorexia. The symptoms of pulmonary strongyloidosis include cough and shortness of breath (Woodring et al., 1994). Up to 75% of people with chronic strongyloidosis have mild peripheral eosinophilia or elevated total IgE levels.

The term “hyperinfection” denotes an unbalanced autoinfection, due to the increased number of worms and their detection at the extraintestinal areas, especially the lungs (Woodring et al., 1996). Hyperinfection affects immunosuppressed patients, in particular, who have a depression of cell-mediated immunity, malignant clinical conditions or chronic illness, also who receive a renal transplantation or with systemic lupus erythematosus, nephritic syndrome (Grove, 1989), rheumatoid and bronchial asthma (Altintop et al., 2010), treated with high-dose and long-term corticosteroids and other immunosuppressants can suffer of it.

Bacterial and fungal infections can occur as a severe consequence because of bowel damage, being frequently the immediate cause of death in patients with hyperinfection and disseminated infection.

Disseminated infection is associated to the migration of larvae beyond the range of normal migratory route, invading numerous organs and including various clinical manifestations, with a possible fatal complication of gram-negative bacteremia (*Streptococcus bovis*, *Escherichia coli*, *Streptococcus faecalis*, *Klebsiella pneumonia*, *Enterobacter* sp.), leading to septicemia, pneumonia or meningitis (Link and Orenstein, 1999; Concha et al., 2005; Cremades et al., 1997).

Several studies have shown a relation between human T-lymphotropic virus-1 (HTLV-1) infection and *S. stercoralis* hyperinfection (Nakada et al., 1984; Newton et al., 1992; Satoh et al., 2002). HTLV-1 patients seem to have an increased risk of acquiring strongyloidosis, preparing to recurrent and severe helminth infections. In patients co-infected with HTLV-1, the high production of IFN γ induces downregulation of IL-4, IL-5, IL-13 and IgE, promoting a switching of immune response from Th-2 to Th-1. The early and effective treatment as well as the *S. stercoralis* infection surveillance in patients with HTLV-1 are important for the prognosis of the coinfection and to prevent recurrent and disseminated strongyloidosis. Furthermore, after treatment, an increase of TNF α and a decrease in sIL-2R levels seem to empower the role of helminth in modulation of HTLV-1 immune response (Salles et al., 2013). Coinfection with HIV and *S. stercoralis* is common in endemic areas. Interestingly, the direct development (homogonic) of *S. stercoralis* is more frequent in HIV patients with normal immune function compared to those with impaired (lower CD4 + cell counts). The homogonic development is fundamental for disseminated infection (Viney et al., 2004). However, the treatment of HIV-infected patients with corticosteroids is an important additional risk factor for *Strongyloides* hyperinfection (Mascarello et al., 2011).

Diagnosis

Diagnosis is made by microscopic examination or via serologic methods.

Microscopic examination and histopathology

The microscopic identification of *S. stercoralis* larvae is done in feces, duodenal aspirates. Biopsy specimens, bronchoalveolar lavage and possibly in the sputum in disseminated infections (CDC). A number of methods has been used to detect larvae in samples, including direct smear of feces in saline-Lugol iodine stain (DS), Baermann (Fig. 2) and formalin-ethyl acetate concentration techniques (FECT), filter paper and agar plate culture (Fig. 3).

The formalin-ether concentration technique (FECT), described by Ritchie, is the most widely used in the clinical practice. The Harada-Mori technique is a filter paper culture technique that uses the water tropism of *Strongyloides* larvae to concentrate them. Compared to FECT and DS, it seems to be more sensitive, but less than Baermann and agar plate methods (Arakaki et al., 1990; Blatt and Cantos, 2003). In the agar culture method, the stool sample is placed on a nutrient agar plate and incubated for at least 2 days. As the larvae crawl over the agar, they carry bacteria with them, creating visible tracks (Arakaki et al., 1990). This method is laborious and time-consuming, but more sensitive than the other procedures (Zaha et al., 2000).

Unfortunately, although the examination of several sample improve the microscopic performance (Sato et al., 1995; Siddiqui and Berk, 2001), most of these methods have low sensitivity, because of the intermittent excretion of larvae and, mainly, the number of larvae in the stool, lower than the detection threshold of the diagnostic tests, especially in chronic infections (Knopp et al., 2001).

Fig. 3 Agar plate culture method. Courtesy of Simona Gatti, University of Pavia, Italy.

Fig. 4 Endoscopic and histopathological findings in a patient with chronic strongyloidosis. Esophagogastroduodenoscopy shows signs of petechial lesions and gastric (A) and duodenal atrophy (B). Histological assessment (H&E; X 200) shows chronic active inflammation with villous atrophy (C) and a large amount of eosinophils around numerous longitudinal and cross-sectioned larvae of *S. stercoralis* (D). From Beltrame A, Bortesi L, Benini M, Bisoffi Z (2018) A case of chronic strongyloidiasis diagnosed by histopathological study. *International Journal of Infectious Diseases* 77: 1–2, with permission.

A cross-sectional study (Khieu et al., 2013) conducted in a semirural village in Cambodia using the Agar plate and Baermann methods on three stool samples, demonstrated that the examination of multiple stool sample is fundamental to achieve a satisfactory level of sensitivity, in absence of a “gold standard.” The sensitivity of Agar plate culture and Baermann was 88.4% and 75.0%, respectively. The negative predictive values were 96.4% and 92.5%, respectively.

According to recent literature, the accuracy of fecal-based methods in terms of sensitivity and specificity was evaluated in a meta-analysis work conducted between 1980 and 2013 (Polanco et al., 2014), which showed that the Agar plate culture and Baermann methods are the most sensitive, comparing to the others conventional diagnostic techniques.

The histological investigation can confirm the diagnosis showing sections of larvae, eggs, some adult worms embedded in the gastric or duodenal crypts and eosinophils infiltrating into the lamina (Fig. 4) (Beltrame et al., 2018).

S. stercoralis infection induces an imbalance between cell death and proliferation, resulting in a disruption of the epithelial kinetics, but the mechanism is still unclear (Werneck-Silva et al., 2006).

Duodenal edematous mucosa, white villi, and erythematous mucosa are reported as abnormal endoscopic findings, whereas thickened folds and mucosal erosions may be seen in the stomach (Thompson et al., 2004).

The study of Kishimoto et al. (2008) demonstrated a major severity of the endoscopic findings in patients with positive biopsies for larvae compared to those with negative biopsies; thus, endoscopic findings are suitable and fundamental markers to establish or support diagnosis, avoiding a fatal outcome.

Serological examination

Serological methods are the most sensitive diagnostic tools (Requena-Méndez et al., 2013). A variety of antigens (crude, purified or recombinant) have been used to detect antibodies against *S. stercoralis*.

Although serological assay have the best potential for point-of-care solution, development of a sensitive serologic tool still remain an important challenge, especially for the cross-reactions with other helminth infections such as filariasis (Norsyahida et al., 2019) and difficult to discriminate chronic from acute infections.

Three tests have shown high sensitivity and specificity; immunofluorescence antibody test (IFAT), the enzyme-linked immunoabsorbent assay (ELISA) and immunoblotting.

IFAT is technically more complex than ELISA and requires a sophisticated equipment for the larval *S. stercoralis* antigen preparation and results interpretation. Recent studies documented decreased antibody titers after a successful treatment, making IFAT test particularly useful for follow-up. IFAT has a 92% positivity for IgG antibodies with no cross-reactivity with other parasitic infections (Korenaga and Bruschi, 2014).

ELISA is the easiest test and is the most widely used technique for the serological diagnosis of strongyloidosis, with sensitivity rates of between 73% and 100% (Requena-Méndez et al., 2013). Many ELISA tests have been used over the years; several in-house ELISAs use crude antigenic extracts of filariform larvae of *S. stercoralis*, *S. venezuelensis* and *S. ratti*. In addition, two commercial kits (Bordier-ELISA and IVD-ELISA) use *S. ratti* and *S. stercoralis*, respectively.

In recent years other two serological tests have been introduced: an ELISA assay based on 31-kDa candidate antigen (NIE), and a luciferase immunoprecipitation test (NIE-LIPS).

NIE is a recombinant 31 kDa antigen derived from L3s of *S. stercoralis*, resulting in a specificity of 87.5% of 48 sera from *Strongyloides*-infected, with no-cross reactivity to *Onchocerca volvulus*, *Loa loa*, and *Mansonella perstans*. In tropical pulmonary, eosinophilia presumably caused by *Wuchereria bancrofti* and false-positive results obtained. NIE could have a potential use as sensitivity skin antigen, because of its capacity to trigger the histamine release from blood of *Strongyloides*-infected patients (Ravi et al., 2002).

LIPS assays, similar to the optimized NIE-ELISA, demonstrated to well-distinguish between *S. stercoralis* and other infections that normally cross-react in standard ELISAs and accurately differentiate between *S. stercoralis*-infected patients from uninfected controls (Ramanathan and Nutman, 2008).

A LIPS assay that uses the antigenic combination of NIE with *S. stercoralis* immunoreactive antigen (SsIR), resulted to have a greater degree of sensitivity (100%) and specificity, compared to the LIPS format using either NIE or SsIR as antigens, with an optimal negative (NPV) and positive predictive values (PPV).

An excellent study (Krolewiecki et al., 2010) reported a comparison between parasitological (agar plate, Baermann, sedimentation concentration, and Harada-Mori) and serological methods (CrAg-ELISA, NIE-ELISA, NIE-LIPS, and NIE-SsIR-LIPS), operating the characteristic receiver operating characteristic curve (ROC) curves to determine the optimal cut-off for each immunoassay based on plotting the sensitivity and specificity. NIE-LIPS showed to be the highest sensitivity and specificity for IgG detection.

Further, a recent meta-analysis demonstrated the accuracy of different serological assays and recommended them for the screening of *S. stercoralis* infection throughout the world. The overall sensitivity, in comparison with stool examination, was 71.7%, ranging from 49.0% to 81.0%, based on different types of *Strongyloides* larvae antigens and dissimilar methods, whereas the specificity ranges from 83% with *S. stercoralis* to 95% with *S. ratti* larvae antigens, respectively (Kalantari et al., 2020).

The diagnostic accuracy of five different serological tests (IFAT, IVD ELISA, Bordier ELISA, LIPS, NIE LIPS) was recently investigated using a composite reference standard (Bisoffi et al., 2014). IFAT was shown to be the most sensitive test, followed by IVD ELISA with a sensitivity of 93.9% and 91.2%, respectively. LIPS was the most specific test (specificity 100%) followed by IVD ELISA and Bordier ELISA.

In general, serological diagnosis have the evident limit of the diminished sensitivity of serum antibody detection in immunosuppressed patients; in case of hyperinfection, due to the immunosuppression, larval output is higher and fecal-based methods are fundamental (Requena-Méndez et al., 2013).

Molecular diagnosis

The molecular biology techniques for the diagnosis are based on the detection of parasite-specific DNA from stool, urine and sputum samples using conventional the polymerase chain reaction (PCR), nested-PCR and real-time PCR techniques (Lodh et al., 2016; Kramme et al., 2011). PCR restriction fragment length polymorphism (PCR-RFLP) analysis has been utilized for phylogenetic and epidemiological studies. The amplification of the ITS1 region in the rDNA gene revealed that the four human isolates from different geographic areas of the world had identical patterns (Nilforoushan et al., 2007).

Other molecular marker is the hypervariable regions in 18S rDNA, which is highly conserved in *Strongyloides* spp. and widely used for molecular taxonomy (Blaxter et al., 1998).

Hasegawa et al. (2009) reported several nucleotide polymorphisms among different *Strongyloides* in the four of the HVRs of the 18S rDNA, resulting in species-specific arrangements.

Moghaddassani et al. (2011) established a single-PCR and nested-PCR for the DNA detection of *S. stercoralis* in fecal samples, previously concentrated in acid/ether solution before the extraction process.

S. stercoralis real-time PCR is another application and important contribution to the accuracy of the molecular PCR-based techniques. A real-time PCR method targeting the small subunit of the rRNA gene was developed for the detection of *S. stercoralis* DNA in fecal samples from northern Ghana, resulting in a higher sensitivity and specificity compared to Baermann and cultural methods (Verweij et al., 2009). However, this PCR design was applied to asymptomatic schoolchildren in Cambodia and showed a sensitivity of 88.9% and specificity of 92.7%, compared to the studies on symptomatic patients (Schär et al., 2013).

The rRNA primes and probe set has been incorporated into multiplex assays on variety of different platforms (Taniuchi et al., 2011). A multiplex real time PCR, focusing on four target parasites (*E. histolytica*, *Giardia lamblia*, *Cryptosporidium* and *S. stercoralis*), proved to be a highly sensitive and specific technique compared to traditional diagnostic methods (Moghaddassani et al., 2011). However, a considerable challenge involved in these methods is the extraction of DNA from larvae of *Strongyloides*. To improve the performance, Repetto et al. (2013) developed an in-house method, which consists in a pre-incubation of the samples with glycine-SDS buffer and subsequent disruption mechanism.

The use of the molecular methods is still limited to the reference laboratories; only a few commercial kits are available and the protocols used are not standardized.

Treatment

Main targets for therapy of *S. stercoralis* infection focus on the complete cleaning of the organism, treatment of symptomatic infections and prevention of the complications related to asymptomatic infections (Nutman, 2017).

According to Center of disease control and prevention (CDC) (www.cdc.gov/parasites/strongyloides/health_professionals/index.html), oral ivermectin (200 mg/kg for 2 days) remains the treatment of choice for uncomplicated infections; in many different clinical trials, conducted between 1994 and 2011, comparing ivermectin with albendazole, ivermectin seemed to be better tolerated with no reports of serious adverse events (Henriquez-Camacho et al., 2016). Potential contraindications to the use of ivermectin include pregnancy, weight <15 kg and suspected or confirmed *Loa loa* infection, which may cause serious side effects.

In case of immunosuppressive patients or with disseminated strongyloidosis, the treatment with ivermectin (200 mg/kg per day) should be recommended until stool or sputum exam is negative for 2 weeks.

Albendazole (400 mg for 3–7 days) is considered an alternative therapy, but is contraindicated in patients with a history of hypersensitivity to benzimidazole and should be avoided in the 1st trimester of pregnancy. The most common adverse effects are headache and elevated liver enzymes. Some other side effects include abdominal pain, nausea, vomiting and fever (Veraldi et al., 2012).

Prevention and control

The best way to prevent strongyloidosis is to cure the personal hygiene, wear protective shoes and avoid contact with fecal matter or sewage (CDC; www.cdc.gov/parasites/strongyloides/health_professionals/index.html).

To minimize the risk of de novo infection and reinfections with *Strongyloides*, serological screening is recommended for immigrants and short-term travelers coming from endemic area, immunosuppressed patients in chronic treatment with corticosteroids and chemotherapy and candidates (donors and recipients) for solid and or bone-marrow transplant.

The updated guidelines from the Infectious Disease Community of Practice of the American Society of Transplantation (La Hoz and Morris, 2019) review the diagnosis, prevention and management of intestinal parasites in the pre- and post-transplantation period. The screening approach is different between endemic and non-endemic areas. In high prevalence endemic area, where laboratories resources are limited, a reasonable approach is to treat all transplant candidates. On the other side, in non-endemic countries, with available diagnostic tools, a targeted screening approach based on epidemiological risk factors for *Strongyloides* infection has been used (Fitzpatrick et al., 2010). Serology is considered the best screening test for living and deceased donors (Abanyie et al., 2015; Requena-Méndez et al., 2017).

Unfortunately, no vaccine has been put into practical use. However, vaccine and passive immunization have been developed and tested on animal model and different antigenic preparations derived from *S. stercoralis*, *S. venezuelensis* and *S. ratti* have been used for vaccine strategies.

Deoxycholate (DOC) soluble proteins, extracted from *S. stercoralis* and combined with aluminum hydroxide adjuvant have been found to induce protective immunity in mice 5 days after infection (Herbert et al., 2002).

Kerepesi et al. (2005) demonstrated for the first time the possible transfer of human protective immunity to mice against *S. stercoralis*. The human IgG were able to bound antigens on the surface and internal in the esophagus of *S. stercoralis* L3s. Combinations of antigens recognized by human IgG and mouse protective antibodies could result potential candidates for a multivalent vaccine. In particular, three antigens (tropomyosin, Na⁺ -K⁺ ATPase and LEC-5) of *S. stercoralis* were identified and the genes were cloned into plasmids for intradermal immunization in the mouse.

Abraham et al. (2011) demonstrated the potential role for a vaccine of a recombinant antigen Ss-IR, which is highly immunogenic in humans and able to generate a protective immunity.

Furthermore, the excretory and secretory component HSP60 produced by all stages of *S. ratti* was investigated as a promising target for the vaccine. Passive immunization of mice with monoclonal IgM anti-HSP60 resulted in a successful immune protection (Nouir et al., 2012).

Closing remarks

Strongyloidosis is an underestimated parasitic public health problem in developing countries.

Although the large number of affected people worldwide, the volume and growth of literature in strongyloidosis are still relatively poor (Waleed, 2019).

Low socioeconomic status and poor sanitation infrastructures are strictly associated with the transmission of the infection. Developing strategies such as the implementation of a preventive healthcare system in low income countries, health education and the adoption of proper environmental controls are fundamental measures to prevent *Strongyloides* infections. Cambodia, for example, benefits from a well-established STH control program and is the first country to reach the 75% national coverage target (Forrer et al., 2019).

Strongyloidosis is considered a silent chronic disease and may be misdiagnosed because of its low parasitic load and uncertain clinical symptoms. The availability of more accurate diagnostic tools is a key element for the performance of more reliable surveys, case control studies and even monitoring for the emergence of drug resistance (Cimino and Krolewiecki, 2014).

A more complete understanding on strongyloidosis and the development of an efficient vaccine are important goal for managing this disease and protecting the communities at risk.

Glossary

Anthelmintic Any chemotherapeutic substance directed against a helminth infection.

Carrier A host that harbors a particular pathogen without manifestations of disease.

Cysticercus The hollow fluid-filled larval stage of *Taenia*, containing a single invaginated scolex.

Definitive host The animal in which a parasite passes its adult existence and/or sexual reproductive phase.

Diheteroxenous Parasite requiring two hosts to complete its life cycle.

Intermediate host The animal that harbors the larval stage of the parasite.

Metacestode A collective term for any of the various larval stages of cestodes which are found in the intermediate host.

Oncosphere The motile, six-hooked embryo (hexacanth) of a tapeworm that is contained inside the egg membranes.
Proglottid One complete unit of a tapeworm, also called segment.
Scolex Attachment end of a tapeworm, commonly referred to as the anterior end which can bear suckers and hooks.
Strobila The chain of proglottids or segments of the tapeworm formed by budding.
Strobilization Process to produce proglottids from the neck region of tapeworms.
Zoonosis Infection or disease naturally transmitted between humans and other animals.

Agents and host involved

Both, taeniasis and cysticercosis are parasitic diseases caused by flatworms belonging to the class Cestoda (tapeworms), family Taeniidae, genus *Taenia*. The adult stages of *Taenia* species cause intestinal taeniasis in the definitive host whilst their larval stages or metacestodes (cysticerci) cause extra-intestinal cysticercosis in the intermediate host.

Humans are the only definitive hosts for the intestinal adults of three *Taenia* species, namely *Taenia solium* Linnaeus, 1758 (the pork tapeworm), *T. saginata* Goeze, 1782 (the beef tapeworm) and *T. asiaticus* n. n. Eom et al., 2020 (syn. *Taenia asiatica* Eom and Rim, 1993) (the Asian *Taenia*). In addition to the adult stage, humans are also intermediate hosts for *T. solium*, consequently suffering not only taeniasis but also cysticercosis. *T. solium* was included in the World Health Organization (WHO) neglected tropical disease (NTD) roadmap in WHO (2012) and this species is also the first on the list of the top 10 foodborne parasites elaborated by the Food and Agriculture Organization (FAO) in FAO (2014).

Other mammals involved in the three *Taenia* life cycles are pigs as intermediate hosts of *T. solium* and *T. asiaticus*, and cattle in the case of *T. saginata*. Cysticerci of *T. solium* have also been molecularly confirmed in dogs and bears (Ito et al., 2002; Theis et al., 1996). A strain of *T. saginata* uses reindeer (*Rangifer tarandus*) instead of bovids as intermediate hosts in northern Russia (Konyaev et al., 2017). There are other *Taenia* species also causing human cysticercosis (*T. crassiceps* or *T. martis* for instance), although these are only sporadically reported (Ntoukas et al., 2013; Eberwein et al., 2013). It has been suggested that *T. asiaticus* could also cause human cysticercosis, but there is no clear evidence so far (Galán-Puchades and Fuentes, 2013a).

Historical background

It is generally estimated that the origin of the association between humans and *Taenia* arose no more than 10,000 years ago, coincidental with the domestication of major food animals such as cattle and pigs and the advent of agriculture (Cox, 2002). Supposedly, at these early stages of animal husbandry, tapeworms circulating in synanthropic cycles between dogs and domesticated ruminants which were the source of *Taenia* parasites that first colonized and then diversified in humans. Another contrasting hypothesis, based on phylogenetic studies using mitochondrial genes, whole mitochondrial genomes, and select nuclear DNA sequences from modern specimens of *Taenia* species from humans and mammalian hosts, revealed that *T. solium* is most closely related to *Taenia* species infecting hyaenids, while *T. saginata* and *T. asiaticus* are most closely related to the species that infects lions (Terefe et al., 2014). This indicates that host switching that allowed *Taenia* spp. to infect humans was likely to be a result of hominids scavenging on the same animals as hyenas, in the case of *T. solium*, and large cats, in the case of *T. saginata*.

Phylogenetic evidence suggests that *Taenia* tapeworms began infecting hominids in sub-Saharan Africa 1–2.5 myr ago, prior to the domestication of animals (Ledger and Mitchell, 2019). Phylogenetic analyses indicate that *T. saginata* and *T. asiaticus* are putative sister species, unrelated to *T. solium*. The divergence between *T. saginata* and *T. asiaticus* is estimated to have taken place 0.78–1.71 myr ago in Africa or Eurasia (Hoberg et al., 2001). The biotic expansion from Africa into Eurasia may have resulted in the isolation and later divergence of *T. asiaticus* in Asia. Eight extant boar species have been identified in South-East Asia. This diversity of potential intermediate hosts in this area may have influenced the intermediate host switch in *T. asiaticus* from herbivore to swine. Therefore, the association of *T. asiaticus* with swine may have been established in Asia following divergence of host populations that later expanded into Europe, being consistent with the dominant distribution of this species in Asian countries (Hoberg, 2006; Michelet and Dauga, 2012).

Taenia spp. have been identified in human remains (pelvic soil and mummified remains) in several locations of Europe, Middle East, Africa and Asia, dated from 8300 BCE to 167 BCE (Ledger and Mitchell, 2019). Particularly in Egypt, the species *T. solium* was immunohistochemically diagnosed in a mummy being dated from the second to the first century BCE. This finding constitutes the oldest on record of the antiquity of this parasite (Bruschi et al., 2006). Likewise, one of the oldest and most famous possible patients suffering from neurocysticercosis (NCC), pathology due to the presence of the cysticerci of *T. solium* in the central nervous system (CNS) that can cause epilepsy, was Julius Caesars (100–44 BCE), who used to suffer headaches and epileptic crises (Bruschi, 2011).

Historically, until *T. asiaticus* was described in Eom and Rim (1993), only two *Taenia* species were considered to parasitize humans, *T. solium* and *T. saginata*. The reason is due to the fact that *T. asiaticus* was confounded with *T. saginata* for more than 200 years in Asia (Eom, 2006); an issue that will be addressed later.

In absence of any available molecular tool, scientists, two centuries ago, were finally able, after failed conclusions, to distinguish between *T. solium* and *T. saginata*. Authors, among others, Grove (1990), Cox (2002) or Wadia and Singh (2002), described the history of human *Taenia* infections in detail.

As already reviewed by Galán-Puchades and Fuentes (2013b), it was not until the mid-19th century that Küchenmeister recognized the differences between *T. solium* and *T. saginata* based on the morphology of the scolex. Leuckart was the first who experimentally showed that proglottids of *T. saginata* fed to cattle developed into cysticerci in calf muscles. Finally, Oliver was the first who discovered that “bladder worms” developed into adult *T. saginata* when ingested by humans.

The first person who demonstrated that pigs are the intermediate hosts of *T. solium* was the Belgian, van Beneden. In 1853, he gave *T. solium* eggs to a pig. When the pig was slaughtered at the abattoir four and a half months later, he found a large number of *T. solium* larvae (named *Cysticercus cellulosae*) in the muscles. Cysticercosis in humans due to *T. solium* was described by Rumler in 1558; however, the connection between tapeworms and cysticercosis had not been made at that time. Around 1850, Küchenmeister, largely criticized for his unethical practices, fed pork meat containing cysticerci of *T. solium* to humans awaiting execution in prison, and after they had been executed, he recovered developing and adult tapeworms in their intestines. By the mid-19th century, it was established that cysticercosis was caused by the ingestion of *T. solium* eggs. Another experimental infection was carried out in the 1930s by the Japanese scientist, Kozen Yoshino (1898–1965), and three more people, who voluntarily swallowed cysticerci from pigs in order to describe the outcomes of the infection (Ito et al., 2020).

The existence of the third *Taenia* species was not considered until the middle of the 20th century. In 1993, the South Korean scientist Keeseon Eom and colleagues provided descriptors of the new species, and have also recently published a complete historical overview of the species in which they proposed a new name for *T. asiatica*, specifically, *T. asiaticus*, according to the Code of Zoonotic Nomenclature (Eom et al., 2020). The origin of the discovery was an epidemiological incongruity observed in Taiwanese aborigines since, although the morphology of the expelled proglottids indicated *T. saginata*, the patients had not eaten beef—cattle being the natural intermediate host of *T. saginata*—but their diet was exclusively based on wild boars and pigs, the intermediate hosts for *T. solium* (Huang et al., 1966; Huang, 1967).

Morphology

Just as the others of the tapeworms belonging to the family Taeniidae, the species of the *Taenia* genus have three stages, two of them are parasite forms, i.e., the adult and the larval stage or metacystode, and the other one, the egg, is a free-living stage. In the definitive host, the intestinal adult stage produces eggs that leave the host and live in the environment for months. When ingested by the intermediate host, the egg turns into a cysticercus-type larva that, in turn, turns into the adult stage when the larva is ingested by the definitive host.

Adults

An adult *Taenia* tapeworm is made up of three parts: a fourth-sucker *scolex* at the anterior smaller part of the worm, behind a short *neck* followed by the *strobila*, a kind of chain comprising hundreds or thousands of hermaphroditic proglottids or segments. Macroscopically, the three species look alike. They are long whitish flat worms looking like tapes (hence tapeworms) (Fig. 1). *T. saginata* is the longest, measuring between 4 and 12 m. Table 1 shows some of the most relevant morphological characteristics of the adult stages of the three human *Taenia* species.

The only way to specifically distinguish them by their external morphology is by means of observing the 1–2 mm sized scolex under a stereomicroscope or a microscope, since only *T. solium* has hooks inserted in the rostellum, a cone-like muscular structure of the scolex that can protrude in some cestodes, but not in the case of *Taenia* species. The presence of hooks in *T. solium* made this species known as the “armed *Taenia*.” Neither *T. saginata* nor *T. asiaticus* have hooks. Therefore, only *T. solium* could be differentiated from the two other unarmed species by the mere observation of a complete adult stage.

Fig. 2 illustrates the morphology of the three scolices; in *T. solium*, the hooks are arranged in two rows of 22–36 characteristically shaped hooks (like a cat claw), including small and large ones, measuring from 11 to 176 µm.

The neck, the part immediately behind the scolex, is the region of growth from where the proglottids of the body, that constitute the strobila, are continuously generated. Actually, a strobila is a kind of factory aimed at the production of eggs. According to the age of the proglottid, the production still has not started (young and immature segments near the neck), the production is in operation (sexually mature proglottids in the middle of the chain) and, finally, at the end of the strobila, the gravid and oldest proglottids, are full of already formed eggs. These latter proglottids are expelled on a daily basis and can be found in human feces. Fig. 3. shows the general internal morphology of a sexually mature proglottid as well as that of the three gravid segments which, once processed at the laboratory (see “Diagnosis” section), by means of counting the number of lateral branches, would allow to distinguish between *T. solium* and *T. saginata*/*T. asiaticus* [these two species present a similar number of branches (Table 1)].

Eggs

The eggs of the three human *Taenia* species have the same morphology (in fact, the eggs of any tapeworm of the family Taeniidae) and, therefore, do not permit species identification. In gravid proglottids, the uterus is full of spherical eggs, measuring 31–43 µm in

Fig. 1 Detail of a fragment of the strobila of *Taenia saginata*.

Table 1 Morphological characteristics of the adult stages of *Taenia* species.

	<i>Taenia solium</i>	<i>Taenia saginata</i>	<i>Taenia asiaticus</i>
Length (m)	1–5	4–12	4–8
Scolex	Armed rostellum	Rostellum absent	Unarmed rostellum
Number of Proglottids	≤1000	>1000	<1000
Number of testes	350–600	800–1200	320–1200
Ovary	Three lobes	Two lobes	Two lobes
Vaginal sphincter	Absent	Present	Present
Number of lateral branches in uterus	7–13	14–32	16–21
Branching pattern	Dendritic	Dichotomous	Dichotomous

Fig. 2 Scolex morphology of the three human *Taenia* species (illustration by Angela DeBenedetti, PhD).

Fig. 3 Up: General morphology of a sexually mature proglottid of *Taenia* spp.; below: uterus morphology of the three human *Taenia* species in the gravid proglottids (illustrations by Angela Debenedetti, PhD).

diameter, presenting an outer embryophore, made up of keratin blocks cemented together, which is thick and radially striated protecting a fully-developed embryo, the oncosphere. This embryo is surrounded by several membranes and possesses three pairs of hooklets, the reason why the oncosphere is also known as hexacanth embryo (Fig. 4, left). The color of the eggs varies between pale yellow and brown.

The eggs of *T. asiaticus* were analyzed by means of electron microscopy and TEM (transmission electron microscopy) as well as SEM (scanning electron microscopy) images, which showed the presence of small vesicles consistent with extracellular vesicles (exosomes and ectosomes) (Galán-Puchades et al., 2016).

The eggs of *T. saginata* (Fig. 4, right) only infect cattle, causing bovine cysticercosis, those of *T. asiaticus* apparently only cause pig cysticercosis. However, the eggs of *T. solium* are infective to pigs as well as to humans, causing not only pig but also human cysticercosis.

Metacestodes

Cysticerci are rounded or oval extra-intestinal metacestodes visible to the naked eye. They are whitish bladders measuring, depending on the *Taenia* species, between 0.2 and 1.5 cm in diameter (Fig. 5). The fluid-filled vesicle has an invaginated scolex which can be seen as a kind of small eccentric and solid granule. In the case of *T. solium*, the vesicular fluid consists of water but also contains calcium, glycoproteins, cholinesterase, and coproporphyrin (Cervantes et al., 1986).

Fig. 4 Left: *Taenia* egg (illustration by Angela DeBenedetti, PhD); right: SEM image of a *T. saginata* egg.

Fig. 5 Left: Morphology of a *Cysticercus cellulosae* with the scolex evaginated (illustration by Angela DeBenedetti, PhD); right: Cysticerci of *Taenia solium* from a pig brain.

Having different specific names for the cysticercus and for the adult stage of the human *Taenia* species is an established habit. The cysticercus of *T. solium* is known as *Cysticercus cellulosae*, *C. bovis* that of *T. saginata* and *C. viscerotropica* for *T. asiaticus*. In the case of *T. solium* and *T. saginata*, when the cysticerci in the intermediate hosts were matched with the adult stages in humans, both had already been differently named, which has remained the same ever since. In the case of *T. asiaticus*, when the species was described, the cysticercus was named differently to keep this habit.

The nature of the intermediate host distinguishes *C. bovis* (cattle) from the porcine cysticerci (*C. cellulosae* and *C. viscerotropica*). *C. bovis*, with a size of 7–10 mm, contains the unarmed scolex of the future adult stage. In the case of cysticerci from pigs, the organ in which the metacestode is found as well as the size and the internal morphology are noticeable. *C. viscerotropica* shows a clear liver tropism, although other less frequent locations should not be ruled out (Singh et al., 2016). The cysticercus of *T. asiaticus* is the smallest, measuring 1.9–3.0 mm in maximum length. Up to 37 rudimentary hooklets on the rostellum can be observed in about 17% of the larval stage of (Eom et al., 2020). *C. cellulosae*, measuring 0.5–1.5 cm, exhibits no defined tropism (Fan et al., 1994), thus developing in muscles and other organs in pigs. Contrary to *C. viscerotropica*, *C. cellulosae* has an armed scolex with the two rows of hooks of the future adult stage in the interior of the cysticercus.

Life cycle

Fig. 6 illustrates the life cycles of the three *Taenia* species and Table 2 shows certain peculiarities of each one of these three cycles.

Fig. 6 Human *Taenia* life cycle: (1) gravid proglottids are shed in feces; (2) pigs (*T. solium*, *T. asiaticus*) and cattle (*T. saginata*) become infected by ingesting the eggs which contaminate water and food; (3) oncospheres from eggs turn into cysticerci in the intermediate hosts (IH); (4) humans acquire taeniasis ingesting raw/undercooked infected meat and/or viscera of the IH with cysticerci; (5) cysticerci turn into adult tapeworms in the human intestine; (6) the adult stage remains in the small intestine where the scolex attaches itself; (7) humans develop cysticercosis through the accidental ingestion of *T. solium* eggs; (8) cysticerci can develop in any organ but most commonly in subcutaneous tissue, the brain (NCC) and eye (ophthalmocysticercosis) (illustration by Angela DeBenedetti, PhD).

The three species have a similar diheteroxenous life cycle. They require two mammalian hosts in order to complete them. Humans are the only known definitive host harboring the intestinal adult stage. In general, on a daily basis or two or three times per week, eggs are shed in the feces of the taeniasis individual, either free or in the interior of gravid proglottids. Gravid proglottids of *T. saginata* and *T. asiaticus* are motile, able to actively force their way out through the anal sphincter, independent of human defecation.

Table 2 Features of human *Taenia* life-cycles.

	<i>Taenia solium</i>	<i>Taenia saginata</i>	<i>Taenia asiaticus</i>
Gravid proglottids release	In short chains of 3–5 segments	Isolated segments	Isolated segments
Movement of the proglottids	No	Yes	Yes
Alternative intermediate hosts	Wild boar, dogs, bears	Reindeer	Wild boar
Larval development (in weeks)	9–10	10–12	4–8
Larval survival	3–6 years	1 year	1–2 months

The eggs can survive in the environment, water or soil, for months, depending on temperature and moisture (see section “Epidemiology and distribution”). A survival of 413 days was reported for *T. saginata* eggs on pasture in Kenya (Duthy and van Someren, 1948).

Once the eggs are ingested by the intermediate host, cattle in the *T. saginata* life cycle and pigs in the case of *T. solium* and *T. asiaticus*, and in contact with hydrochloric acid, digestive enzymes and bile, the blocks of the embryophore become unglued, thus liberating the oncosphere which penetrates the intestinal wall reaching the blood or lymphatic vessels of the mesentery. Subsequently, these post-oncospheres are passively transported to several host tissues in which they will develop into the larval or metacystode stage, the cysticerci, in several weeks (Table 2). When humans eat raw or undercooked infected meat or viscera of intermediate hosts (beef and pork), in the upper part of the small intestine, the scolex evaginates out of the cysticercus, becomes attached to the mucosa with the aid of the suckers (and hooks in *T. solium*), and by gradual strobilization develops into adults in several weeks.

The adult life span of *Taenia* species is not clearly known. The life span of *T. solium* is controversial. Although longevity of up to 25 years was accepted for years (Hoberg, 2002), a shorter life span of less than 5 years has also been suggested (Lightowlers, 2010; García et al., 2014). In the case of *T. saginata* and *T. asiaticus*, cases in which infections persisted for decades have been recorded (Wright and Jain, 1984; Eom et al., 2020).

In addition to taeniasis, humans may develop cysticercosis by means of the ingestion of *T. solium* eggs, acting then as intermediate hosts. Unfortunately, the CNS is one of the main target organs of cysticerci in humans; this infection produces a complex disease, NCC.

Epidemiology and distribution

There are numerous articles in the literature that describe a great variety of aspects of the epidemiology of human taeniasis/cysticercosis. Only considering those most generalist published in the last 20 years, is worth mentioning the papers by Eom and Rim (2001), Flisser (2002), Hoberg (2002), Pawlowski (2002), Ito et al. (2003), Murrell (2005), Devleesschauwer et al. (2012), Zammarchi et al. (2013), Coral-Almeida et al. (2015), Ito et al. (2016), Laranjo-Gonzalez et al. (2017), Wu et al. (2017), Braae et al. (2018), Trevisan et al. (2018), Bucur et al. (2019), Dixon et al. (2019), Abraham et al. (2020), Eichenberger et al. (2020), among others, are noteworthy.

The epidemiology of the human *Taenia* species depends on two basic factors: the natural ecology of the life cycle and the artificial changes introduced by humans in that ecology. The high biotic potential of the adult stages (great ability to produce eggs), the increase of host populations (humans, pigs and cattle), changes in livestock production, high consumption rates of undercooked meat, as well as the inherent consequences of globalization, i.e., progressively more intensified contacts between hosts due to human migratory movements, in addition to the role of international trade, make taeniasis a progressive zoonosis.

Parasite populations of these three species comprise three subpopulations: The adult stage in humans, the released eggs in the environment and the metacystodes in the intermediate hosts. Therefore, three epidemiological factors determine the geographical distribution of taeniasis/cysticercosis: (a) the human factor; (b) the environment; and (c) the type of livestock.

Taenia solium distribution

The pork tapeworm has a cosmopolitan distribution being infrequent in those regions where pork is not consumed. *T. solium* is an endemic parasitic disease in many countries of Central and South America, South Africa and Asia. Its prevalence varies according to the epidemiological factors, i.e., the level of sanitation, pig husbandry practices (pigs scavenging for food), limited veterinary meat inspection and eating habits. In endemic regions, large portions of the population may be infected. In these areas up to 6% of people may harbor intestinal worms at a given time and serve as a source of infectious eggs that cause cysticercosis (Allan et al., 1996).

Out of more than 190 countries analyzed by WHO, only 20% were non-endemic (there is no data from 47% of the countries) (<https://apps.who.int/gho/data/node.main.NTDT SOL1?lang=es>; last updated 2018-12-12). Worldwide about 66 million people are estimated to be infected with *T. solium*, mainly in Sub-Saharan Africa, Latin America and South and South-East Asia (Pal et al.,

2018). According to a systematic review carried out in endemic countries in 2015, the estimates for the prevalence of circulating *T. solium* antigens or antibodies for Africa, Latin America and Asia were: 7.30%, 4.08% and 3.98%, respectively. Seroprevalence estimates of *T. solium* antibodies were 17.37%, 13.03% and 15.68%, respectively. Taeniasis reported prevalences ranged from 0% to 17.25% (Coral-Almeida et al., 2015).

Since routine diagnostic methods to identify human taeniasis lack specificity and usually cannot differentiate among the three species (see “Diagnosis” section), the true burden of *T. solium* taeniasis estimated by those techniques can only be an approximation. On the contrary, if serodiagnostic methods are employed, its prevalence may be an overestimate of its real prevalence due to transient antibodies. In fact, and due to its public health importance, the NCC burden has been analyzed by two different research groups. NCC-associated epilepsy Disability Adjusted Life Years (DALYs) were estimated at 0.5 million by The Global Burden Disease. However, the WHO’s Foodborne Disease Burden Epidemiology Reference Group obtained a much larger estimate at 2.8 million (Carabin et al., 2017). The total number of people suffering from NCC, including symptomatic and asymptomatic cases, is estimated to be between 2.56 and 8.30 million (OPS, 2019). These contrasting results reveal uncertainties regarding the epidemiology of *T. solium*.

Improved pig rearing conditions seem to have eliminated the parasite in most Western European countries. However, little is known about the current true endemicity status of *T. solium* throughout Europe. Although autochthonous *T. solium* taeniasis/cysticercosis may be possible in Europe, peer-reviewed literature does not provide sufficient information on the current endemicity status of *T. solium* in Europe (Devleeschauwer et al., 2017). Indeed, only a few case reports were available from Eastern European countries.

According to Cantey et al. (2014), data on the prevalence of taeniasis, or adult tapeworm infection, in the United States is scarce. The few population-based taeniasis studies suggest prevalence may be 0.5–3% in selected populations. Moreover, there is also a lack of data on the seroprevalence of cysticercosis in the United States. The limited understanding of the NCC burden is caused by multiple factors, including the fact that the disease is only reportable in Arizona, California, New Mexico, Oregon, and Texas.

Although *T. solium* is no longer endemic in industrialized nations, where livestock is raised commercially with regulations to ensure minimal contact with human feces, the prevalence there has been increasing in recent years due to immigration. Also, specific identification has increased due to improved diagnostic techniques.

Taenia solium epidemiology

The human factor

The tapeworm life cycle is propagated via foodborne and fecal-oral transmission (Fig. 7). Consumption of uninspected pork meat is the major source of human *T. solium* taeniasis. To circumvent the requisition of infected pigs, owners of a small number of pigs, especially in rural areas, use them for their own consumption or they are illegally sold, thereby escaping control (Murrell, 2005). In addition to an inadequate inspection of pork, other risk factors for infection include age, open sewers and improper disposal of human feces, poor education, and the inability to recognize infected pigs. Local techniques for food preparation can also influence the spread of the disease.

Although humans usually harbor only one intestinal adult, multiple infections can be higher than 40%, reinfection being a common phenomenon in meat eaters. Although it has been accepted that taeniasis is more frequent among individuals between

Fig. 7 Graphical scheme of *Taenia solium* transmission.

Fig. 8 Graphical scheme of *Taenia saginata* transmission.

20 and 40 years of age, a study in the Democratic Republic of Congo revealed that the highest positivity was found in the 5–10 year age group (Madinga et al., 2017).

Human travel and migration undoubtedly favor the spread of the parasite considering that human taeniasis usually occurs asymptotically. Infected individuals may even be unaware of their condition, since gravid proglottids are shed only by defecation, therefore, probably being unnoticed by the patient.

Cysticercosis, in pigs as well as in humans, occurs following the ingestion of eggs. The very high fecundity of the tapeworms facilitates this transmission, that in the case of human-to-human (Fig. 8), can be caused by the accidental ingestion of eggs contaminating food and water as well as by eggs directly ingested via dirty hands. This person-to-person transmission explains the presence of human cysticercosis cases among people who, for religious or dietary reasons, do not consume pork (Schantz et al., 1992).

Regarding NCC, the majority of infected individuals is between 20 and 50 years of age (Hoberg, 2002). People do not need to harbor an intestinal worm to acquire cysticercosis since it is caused by the ingestion of eggs, but about 15% of patients with NCC do harbor a tapeworm at the time of diagnosis (García et al., 1999; Gilman et al., 2000) and 25% report having had one at some point (Dixon and Lipscomb, 1961). External auto-infection (anus-hand-mouth) seems to be more probable than internal auto-infection by reverse peristalsis of the intestine (Murrell, 2005), although prevalence of antibodies to oncospheres suggests that this may occur more frequently than previously thought (Bowman et al., 2006). Extraordinarily, cysticercosis can even be acquired by bizarre medical practices that ignore the infective ability of the eggs (Bourke and Petana, 1994).

The environment

The uterus of a gravid proglottid of *T. solium* can harbor up to 55,000 eggs. The segments are detached from the strobila in groups (Table 2). Thereby, *T. solium* can shed up to 300,000 eggs per day into the environment (Pawlowski, 2002).

According to the Environmental Classification of excreta-related infections elaborated by WHO (2004), *T. solium* and *T. saginata* belong to Category IV, i.e., latent and persistent infection; pigs and cattle as intermediate hosts and successful transmission.

The survival of parasites outside the gastrointestinal tract of the host depends on the environmental conditions. There are many abiotic and biotic variables that affect the eggs. Among them there are physical factors (temperature, sunlight, humidity, etc.), chemical ones (ammonia, salt, acids, etc.) as well as biological ones (fungi, protozoa, and invertebrates) (WHO, 2004). Factors influencing egg survival and infectivity have been studied in several members of the genus *Taenia*. Infective *Taenia* eggs can survive for up to 9 months in the environment. However, temperatures above 60 °C, pH 12 and desiccation lead to rapid death of the eggs. Conversely, humidity and temperatures above 10 °C and room temperature favor egg survival. A number of agents such as wind, water and some invertebrates and birds are believed to aid taeniid egg dispersal (Pawlowski, 2002). *Taenia* eggs are able to survive in sludge. As a consequence, a potential route of transmission is the irrigation of pasture with wastewater or using domestic sludge as fertilizer for soil.

Livestock: Pigs

The third link of the epidemiological chain is livestock as reservoir of the disease. Pig cysticercosis considerably affects pork meat quality and entails substantial economic losses in the affected areas where *T. solium* is endemic. In these endemic areas, *T. solium* porcine infections have been associated with poverty, absence of latrines and free access of scavenging pigs to human feces. In many low income countries, pigs are usually poorly fed, are not confined and are allowed, and even encouraged, to roam about free in search of food. These free roaming pigs, in combination with the generalized practice of open-air fecalism that prevails, end up ingesting a significant amount of human feces, some of which are contaminated with *T. solium* eggs. In the worst social conditions, pigs are deliberately placed to graze in terrains used for public defecation or near rural out-houses. In rural areas, piglets become

infected at the age of 4 weeks, i.e., immediately after weaning. In tropical areas, infection in piglets is higher during the dry and hot season; this paradox arises from adult animals being reluctant to move at high temperatures, whilst piglets remain active (De Aluja et al., 1998), and, as a consequence, have easy access to fecal material during the hot season.

The prevalence of porcine cysticercosis in endemic countries usually varies between 0% and 56.6%, 1% and 61%, and 0.02% and 77% in Africa, Latin America and Asia, respectively (Murrell, 2005; Wu et al., 2017). *T. solium* has been eradicated in the European Union (EU), primarily due to the change toward industrial pig farming, in which the animals are raised in controlled housing conditions with no outside access. Thereby, the probability of pigs feeding on human feces is very low. However, since 2007, according to the European Food Safety Authority (EFSA), cysticerci consistent with *T. solium* have been detected in pigs slaughtered in five countries of the EU (Austria, Estonia, Lithuania, Poland and Romania) (EFSA, 2010). The entry of tapeworm carriers into the EU seems a lot more plausible than the import of infected pork (Gabriel et al., 2015).

Taenia saginata distribution

The most common and widely distributed human *Taenia* tapeworm is *T. saginata*. Infection in humans has been reported in 45 countries and 45–60 million people are affected (Pal et al., 2018). *T. saginata* is common in cattle-breeding areas of the world. The areas with the highest prevalence (up to 27%) are found in Central Asia, the Near East, and Central and East Africa. Areas of lower prevalence (<1%) are found in Europe, Southeast Asia, Central America, and South America. Consumption of “measly” (cyst-infected) raw or undercooked beef is the usual means of transmission. Rare steak or kebabs and steak tartare are dishes typically associated with *T. saginata* infection.

Data published between 1990 and 2017 on *T. saginata* taeniasis and cysticercosis occurrence and prevalence in Europe, America, Asia and Africa has been gathered by The European Network on Taeniosis/Cysticercosis (CYSTINET) (<https://www.biomedcentral.com/collections/GDTS>).

Taenia saginata epidemiology

The human factor

As in the case of *T. solium*, the tapeworm life cycle is propagated via foodborne and fecal-oral transmission (Fig. 8). Unlike *T. solium*, the eggs of *T. saginata* are only infective for cattle and not for humans. Therefore, taeniasis *saginata* in humans is not the serious public health threat that taeniasis *solium* is, although the economic burden of bovine cysticercosis should not be underestimated.

Human taeniasis results from the consumption of contaminated beef that has not been frozen or thoroughly cooked containing viable *Cysticercus bovis*. In pastoral societies raw or rare meat is part of the normal diet, however, *T. saginata* taeniasis is, in many developed countries, also associated with the increased consumption of raw and rare beef.

Taenia saginata has been reported in children below 1 year of age as well as in adults over 80, although infection is most common in the 20–40-year age group.

There are three main patterns of transmission of *T. saginata*: (i) hyperendemic, characterized by pastoral farming in areas with a high prevalence of human *T. saginata* taeniosis and bovine cysticercosis; (ii) endemic, characterized, by the existence of a small number of human carriers, a wide dispersal of eggs in the environment and a moderate prevalence of bovine cysticercosis mostly of low intensity; and (iii) epidemic, characterized by feedlot situations in which a single human carrier, whose close contact with a herd of susceptible cattle can result in a massive outbreak of bovine cysticercosis (Murrell, 2005).

The environment

In the epidemiology of *T. saginata*, the presence of eggs in perianal zones, clothes, hands, as well as the shedding of gravid proglottids independent of defecation (up to five to 15 per day) cause humans to contaminate the environment to a greater extent than in the case of *T. solium* taeniasis.

T. saginata eggs have been found to survive in the environment for several months. In a damp temperate climate, the eggs of *T. saginata* can survive in the environment for about 10 months, remaining viable for 130 days in water, which represents a major way of dissemination of the eggs (Murrell, 2005). Eggs could be activated after 4 months of being kept in a stream of water at temperatures ranging from -10°C to 17°C , as well as after 1 week of constant freezing at -18°C , or repeated freezing and thawing from -6°C to 5°C . Therefore, *T. saginata* eggs can survive in cold environments, such as the Northern European winter, and pose a significant risk of transmission (Bucur et al., 2019).

There are several ways in which the eggs of *T. saginata* can become available to cattle through sewage. In systems which use primary settling tanks, grit tanks, sedimentation tanks or aeration tanks, eggs in the effluent will pass through these systems into rivers or farms using sewage. Flooding of the rivers will ensure that the eggs are dispersed onto livestock pastures. If the outlet falls directly into the sea from a raw sewage collection plant, segments will be present and the eggs can then be disseminated onto pastures by birds.

Livestock: Cattle

According to Taylor et al. (2007), in cattle, there are two quite distinct epidemiological patterns found in low income and industrialized countries, respectively. In certain parts of Africa, Asia and South America cattle are reared on an extensive scale, frequently human sanitation is poorly developed and cooking fuel is expensive, which leads to a high level of human infection with

T. saginata (up to 20%). As a consequence, cattle are usually infected in early life, often within the first few days after birth. Based on routine carcass inspection, the infection rate is often around 30–60%, although the real prevalence is considerably higher.

In industrialized countries (mainly countries of Europe, North America, Australia and New Zealand), the standards of sanitation are high and meat is carefully inspected and generally thoroughly cooked before consumption. In such countries, the prevalence of bovine cysticercosis is low, being less than 1% of carcasses inspected. Occasionally however, a cysticercosis “storm,” in which a large proportion of cattle is infected, has been reported on certain farms. In Britain and Australia, this has been associated with the use of human sewage on pasture as a fertilizer in the form of sludge, i.e., sedimented or bacterial-digested feces. Other causes of a sudden high incidence of infection on certain farms are due to a tapeworm infection in a stockman occurring either as a random event or as the result of the presence of migrant labor from a country with a high prevalence of infection.

***Taenia asiaticus* distribution**

So far, *Taenia asiaticus*, also known as the Asian *Taenia*, shows a geographical distribution exclusively linked to the Asian continent, and was primarily found only in South-East Asian countries. However, with the introduction of molecular methods in epidemiological studies, its far more extensive geographical distribution was laid bare. Hitherto, the species has been found in Korea, Taiwan, the Philippines, China, Thailand, Indonesia, Vietnam, Japan, Lao PDR, Nepal and India (Eom et al., 2020). In Bangladesh, its presence is suspected but it would require molecular confirmation. *T. asiaticus* prevalence can reach up to 21% and is even becoming the dominant human *Taenia* tapeworm in several countries (Eom et al., 2009).

Considering that *T. asiaticus* has cosmopolitan hosts (humans and pigs), it seems strange that globalization has not affected it (Galán-Puchades and Fuentes, 2014). The lack of identifying this parasite outside Asia is probably due to misdiagnosis since eggs as well as gravid proglottids, have the same morphology as *T. saginata*. Therefore, unless molecular techniques are applied in diagnosis, *T. asiaticus* can easily be confounded with *T. saginata* outside Asia as, aforementioned, was the case in Asia for more than 200 years (Eom, 2006).

***Taenia asiaticus* epidemiology**

The human factor

According to the clear hepatic tropism of the cysticercus of *T. asiaticus* in pigs, the main risk factor for humans is the consumption of raw or undercooked infected pork liver or foods containing it. Although the consumption of pork liver is generally less popular than that of pork meat, this liver tropism does not seem to be the reason of its, so far, exclusively Asian distribution, since pork liver is a cheap and ubiquitous food consumed in whatever non-Islamic country and Israel (Fig. 9). The possibility of becoming infected when consuming raw or undercooked pork meat also exists since cysticerci of *T. asiaticus* have also been found in the muscles of naturally infected pigs (Singh et al., 2016).

Fig. 9 Pork liver trays in a Spanish supermarket.

In Asian countries, the transmission of *T. asiaticus* is often related to social, cultural, and religious practices that entail the consumption of raw pork liver. Ale et al. (2014) reviewed the different ethno-geographical foci where *T. asiaticus* has been studied. The consumption patterns could explain the fact that prevalence increases with age and its apparent predominance in males.

For more than 30 years, the passing of motile proglottids from carriers has been reported in 3% of all cases (Eom et al., 2020). It is still not known whether *T. asiaticus* eggs are able to produce human cysticercosis (Galán-Puchades and Fuentes, 2013a).

The environment

No specific study has been carried out on the survival or dispersal agents of *T. asiaticus* eggs, although the same results obtained with other taeniid eggs could be expected for this species.

Livestock: Pigs

T. asiaticus grows to young cysticercus in the visceral organs of pigs within 1–2 months after the ingestion of the eggs. The metacestodes are mainly found in the liver parenchyma and to a lesser extent on the liver surface. Other viscera, such as lungs, omentum, serosa and mesentery, may also harbor cysts (Eom et al., 2020). *C. viscerotropica*, as already mentioned, has also been found in the muscles of pigs, which increases the likelihood of human infection.

Pork is a staple of the diet in South-East Asia. In fact, it is a common practice in many rural parts to house pigs and other animals under the floor of the house, creating an ideal environment for its transmission. Consumption of pork meat and viscera was far more common than that of beef, yet *T. solium* had a surprisingly low prevalence compared to *T. saginata* in certain Asian countries. This epidemiological paradox led investigators to hypothesize that another *Taenia* parasite might be present, closely resembling the *T. saginata* morphology but the *T. solium* life cycle, and, hence, *T. asiaticus* was subsequently classified (Eom et al., 2020).

In spite of the presence of *T. asiaticus* human taeniasis in 11 Asian countries, according to the literature search carried out by Braae et al. (2018) in certain countries of East and South-East Asia, the presence of *T. asiaticus* porcine cysticercosis was only confirmed in one country (Lao PDR). However, Simanjuntak et al. (1997) found that approximately 23% of pork liver samples in Bali, Indonesia, harbored *T. asiaticus* metacestodes and 1.01% was found in South Korea (Eom et al., 2020).

The scarcity of data indicates that *T. asiaticus* porcine cysticercosis is vastly underreported, and that more epidemiological survey data are required in order to determine the burden of this parasite within Asia as well as in the rest of the world. Due to the small size of the cysticerci and their location in pigs, routine post-mortem inspection lacks sensitivity, making the disease practically undetectable. In experimental infections, 88.9% of the small cysticerci were located in the hepatic parenchyma. Consequently, unless slices of 2–3 mm were made, cysticerci could not be found in livers, and this procedure is not carried out in any routine inspection. This scenario makes it currently almost impossible to determine if the parasite is present or not on a worldwide scale (Galán-Puchades and Fuentes, 2014).

Clinical aspects and human response to the parasite

Taeniasis

Taeniasis is generally a silent disease. In spite of the size of human *Taenia* spp. and regardless of the species involved, intestinal taeniasis is usually asymptomatic. Only mild and non-specific symptoms are described as associated to intestinal taeniasis. Among those infected with *T. saginata*, the most common sign of the disease is the unpleasant sensation due to the discharge of proglottids, independent of defecation. Abdominal pain, nausea, diarrhea or constipation, changes in appetite, weakness, weight loss, pruritus at the perianal area, and general malaise are other symptoms that a small number of patients experience. On occasions, neuropsychiatric disturbances usually appear after diagnosis, when the patient is aware that a several-meter long parasite inhabits his/her intestine.

Exceptional symptoms gathered from literature include toxic effects due to metabolites of the parasite, Binge Eating Disorder (Fernández-Aranda et al., 2000) and iron deficiency anemia (Shorbagi et al., 2012). Wani et al. (2018) and Karanikas et al. (2007) described, respectively, two cases of bowel obstruction due to *T. saginata* and the latter also reviewed other rare complications such as acute obstruction of the Wirsung duct and pancreatitis, gangrenous cholecystitis, Meckel's diverticulitis, acute abdomen following rupture of a liver abscess caused by the presence of *T. saginata* in the right lobe, acute appendicitis and cholangitis.

There are only few studies on the immune response in patients suffering from taeniasis. By contrast, numerous studies have been made on cysticercosis to determine the mechanisms of immune response directed against the cysticerci of *T. solium*. Recently, Prodjinotho et al. (2020) reviewed the host immune responses during NCC infection. This response to the cyst is remarkably complex and diverse. The immune response to the parasite is of type 2 as observed in the majority of affected individuals with asymptomatic infection, however, it can change during symptomatic diseases. Regarding humoral responses in NCC, several antibody classes are produced during the clinical course of NCC, with the most prominent being IgG in serum and CSF. In extraparenchymal infection, increased levels of Ig G, IgM, and IgE were observed in symptomatic patients (Prodjinotho et al., 2020).

Cellular immune responses during NCC are diverse and distinct with regard to the localization and stages of parasite in the brain and mostly limit the progression of the disease. After months to years in the brain tissue, the cysticerci start to degenerate, either naturally or due to anthelmintic treatment, and lose their ability to regulate the host response. Thus, an inflammatory immune

response characterized by an increase in interleukin 1 beta, tumor necrosis factor alpha, and interferon gamma production is instigated (Prodjinotho et al., 2020).

Regarding the interaction with the host, *T. solium* is the species that deserves more attention considering that its adult stage produces the eggs, i.e., the source of human and pig cysticercosis infection. Due to the scolex fixation by means of the suckers and the hooks, there is local damage and an inflammatory response in the upper small intestine that involves mast cells and goblet cells and varied cell populations including plasma cells, lymphocytes, neutrophils and eosinophils (Willms, 2008). Stage-specific antibody responses have been identified in serum from *T. solium* tapeworm carriers. However, considering that humans can suffer from taeniasis and cysticercosis at the same time, it is difficult to determine whether the antibodies detected could be due to the adult or the larval stage (Correa and Medina, 1999).

Human tapeworm carriers are the main risk factor for acquiring cysticercosis. Since humans are the only definitive hosts, different experimental models of *T. solium* taeniasis have been explored in order to study humoral and cellular immune responses in the intestinal mucosa, mesenteric lymph nodes, spleen, serum, saliva and feces of experimental hosts for immunodiagnosis and vaccine development (Flisser et al., 2010).

Cysticercosis

When humans accidentally ingest *T. solium* eggs, within 2 h of liberation, oncospheres enter submucosal blood and/or lymphatic vessels and migrate to a number of internal organs. *T. solium* cysticercosis can occur in almost any part of the body. In humans, cysticerci are most commonly found in skeletal muscles and in the CNS (NCC), mainly in the brain although they can also be found in the skin, subcutaneous tissue, eye (ophthalmocysticercosis), and heart. Although embryos are distributed to all tissues, they are commonly destroyed by the human immune response, thus surviving, preferentially, in the brain and eye (García et al., 2020).

Cysticerci in humans (and pigs) can be found in different morphological states; some are clearly cystic with intact structures (vesicular) while others seem coagulated and their structures somewhat disassembled (colloidal), or, they may be necrotic and sometimes calcified, partially or totally (calcified) (Sciutto et al., 2000). All these forms of the cysticerci possess the potential of causing functional disturbances due to space occupation and/or local inflammation. Viable cysticerci have been shown to use multiple active mechanisms of immune evasion even covering themselves with host immunoglobulins (García et al., 2020).

When located in the tissues, cysticerci are rarely symptomatic unless they encyst in the eye or in the CNS.

Cysticercosis out of the CNS

Cysticercosis can cause subcutaneous nodules in the skin that, occasionally, become swollen and painful. In muscles or viscera, they do not seem to cause any apparent clinical manifestation beyond detectable masses, although muscular pseudohypertrophy when there is a very high worm burden in skeletal muscles has occasionally also been reported. Cysts in the heart are apparently asymptomatic in most cases and are mostly found in patients with disseminated cysticercal infections (Vaidya et al., 2013). Disseminated cysticercosis, a rare complication of the disease with the involvement of almost any organ of the body, has more frequently been reported in immunocompromised than in immunocompetent patients (Banu and Veena, 2011; Gnanamoorthy and Suthakaran, 2019).

Conversely, ophthalmic cysticercosis is frequently a clinical problem. Ophthalmocysticercosis is the most common intra-orbital parasitic infection. Ocular and orbital cysticercosis has varied clinical manifestations depending upon the site of involvement, stage of the cyst and the host-immune responses. The infection may involve the sub-retinal space, extra-ocular muscles, eyelid and/or lachrymal glands surrounding the eye. The most frequent symptoms are pain in the eyes, blurriness, partial or complete loss of vision and, in extreme cases, complete detachment of the retina. A study, in which 171 patients suffering from orbital cysticercosis were involved, revealed periocular swelling, proptosis, ptosis and diplopia as the main symptoms (Rath et al., 2010).

With the advent of the new imaging techniques, ocular and orbital cysticercosis is now increasingly diagnosed even in non-endemic zones (Dhiman et al., 2017).

Neurocysticercosis

NCC, the infection of the CNS by the metacestode of *T. solium*, is the most common helminthic neurological infection and a major public health problem in most parts of the world, still being a major cause of acquired epilepsy in most low-income countries. In endemic settings, approximately 30% of all epilepsy is due to NCC (WHO, 2016). This causes 50,000 deaths/year, and many of the people affected suffer from active epilepsy, with all the social and economic consequences that this implies (García et al., 2005).

In addition to the cysticerci with the same morphology as those from pigs (cellulose cysticercus), a racemose cysticercus can grow exclusively in the human brain. These peculiar cysticerci show a larger size (10–20 cm), being rounded or lobulated and, importantly, without scolex. These racemose cysticerci usually occur in extraparenchymal sites (e.g., subarachnoid space, meninges). The absence of the scolex is believed to be the result of hydropic degeneration caused by the continuous adsorption of cerebrospinal fluid (Del Brutto, 2002). Between the cellulose and the racemose forms, intermediate forms of cysticerci can also be found in human brains (Rabiela et al., 1989).

NCC is highly pleomorphic and there is no possibility to define a pathognomonic clinical syndrome (Del Brutto, 2013). The clinical presentation of NCC is varied and depends on the stage, number, size, form and location of the larval stages within the CNS and the host's immune response to the parasite. Thus, NCC can be classified following different criteria (Mahanty and García, 2010; Ferrer and Gárate, 2014): (i) cysticerci location: *intraparenchymal* (the most common form) and *extraparenchymal* (subarachnoid

space, ventricles, or spinal cord); (ii) viability of the cysticerci: *viable or active* (single, multiple, massive), *transitional or degenerating* (single, multiple, massive), and *calcified or inactive* (single, multiple); (iii) the evolutionary stages of parenchymal lesions as evidenced by neuroimaging techniques: *viable or vesicular form* (small single or multiple lesions), hypodense rounded images, with a hyperdense nodule inside (scolex), lacking surrounding edema. *Colloidal*, lesions surrounded by edema representing the acute encephalitis phase in which the host's immune system reacts against the parasite. *Nodular-granular*, hyperdense lesions surrounded by edema, referred to as "cysticercus granuloma." *Calcified lesions*: small hyperdense nodules without perilesional edema, being the most common finding in NCC.

Therefore, depending on the location, number and type of cysticerci in the CNS, clinical manifestations can vary from completely asymptomatic infection to severe disease and death. Generally, most of patients with parenchymal brain cysticercosis develop seizures as the main or sole manifestation of the disease. Viable cysts are able to survive for years or even decades with intermittent neurological symptoms. Conversely, extra parenchymal NCC has a direr prognosis. Those patients presenting the subarachnoid and ventricular forms of the disease often display focal neurological deficits (paralysis of extraocular muscles, hearing loss, facial nerve palsy or trigeminal neuralgia, and focal neurological symptoms related to brainstem impairment), acute intracranial hypertension secondary to hydrocephalus, ischemic cerebrovascular complications and cognitive decline.

Racemose cysts usually are encountered in the basal cisterns and can cause an intense inflammatory reaction, fibrosis, and progressive thickening of the leptomeninges at the base of the brain; it is also usually an obstruction of the cerebrospinal fluid circulation, resulting in hydrocephalus and intracranial hypertension as a consequence of the unrestricted growth of the racemose parasite. Mortality rates can reach up to 20% in those who do not receive optimum treatment (Ferrer and Gárate, 2014; García et al., 2014). However, NCC prognosis has apparently improved thanks to better diagnostic techniques and improved disease management.

Other presentations of NCC are subdural and spinal. Radicular pain, weakness, and sensory deficits are common in patients with cysticercosis of the spinal cord (García et al., 2014).

NCC might, in fact, present any neurological symptom, but other manifestations more frequently seen are headache, nausea, vomiting, ataxia, confusion, associated stroke, or involuntary movements (Ferrer and Gárate, 2014; García et al., 2014).

Diagnosis

Taeniasis

Specific diagnosis of human taeniasis is mainly required in order to detect *T. solium* carriers, the source of infection of human cysticercosis. Thomas (2015) analyzed the different diagnostic assays for *T. solium* pointing out their benefits as well as their barriers.

Historically, taeniasis has been diagnosed by microscopic examination of human feces with the aim of finding parasite eggs and/or proglottids. Considering the intermittence in eggs/proglottids excretion, this microscopic method lacks sensitivity. In addition, the finding of eggs only reveals the presence of a tapeworm of *Taenia* genus since the morphology of the eggs of the three human species is the same. Concentration methods, particularly those using sedimentation, increase the diagnostic yield; however, the overall sensitivity of serial stool exams using concentration methods is still suboptimal (García et al., 2020). In fact, the reported sensitivity of microscopy ranges from 0% to 59% (Zammarchi et al., 2017).

The study of well-preserved gravid proglottids allows distinguishing between *T. solium* and the complex *T. saginata/asiaticus*. Proglottids can be pressed between glass slides to count the number of lateral branches (7–13 branches for *T. solium* and 14–32 for *T. saginata/asiaticus*) (Table 2) after India ink injection staining through the genital pore or some other clearing method. If the scolex were retrieved, the presence of the rostellar hooks could also enable the differentiation of *T. solium* from *T. saginata/asiaticus*, but the scolex is rarely available. There are some other morphological differences in mature proglottids to distinguish *T. solium* but the morphological identification of mature proglottids requires laboratory facilities and trained personnel.

Specific techniques to differentiate *Taenia* species include enzyme electrophoresis (glucose phosphate isomerase zymograms), molecular methods [different types of polymerase chain reaction (PCR) (Yamasaki et al., 2004; Mayta et al., 2008; Ng-Nguyen et al., 2017), loop mediated amplification method (LAMP) (Nkouawa et al., 2010), LAMP in combination with dot enzyme linked immunosorbent assay (dot-ELISA) (Nkouawa et al., 2016)] and coproantigen ELISA (CoAg-ELISA). A *T. solium* species-specific CoAg-ELISA (Guezala et al., 2009) showed high sensitivity and specificity. Unfortunately, it is experimental, and rarely available except to those working in this field. Similarly, neither enzyme electrophoresis nor molecular methods are available in most laboratories.

Summarizing, the following tools are recommended for the diagnosis of *T. solium* taeniasis (Zammarchi et al., 2017): (i) investigating the history of proglottid expulsion within the past year, with the support of visual materials to help the subject identify the proglottids; (ii) microscopic and macroscopic examination of stool samples collected on three different days; (iii) *Taenia* species identification should always be performed, especially in subjects exposed to *T. solium* in highly endemic countries (Latin America, Asia and Africa).

Cysticercosis

Cysticercosis out of the CNS

Palpable subcutaneous nodules can sometimes be felt and diagnosis is confirmed by biopsy. X-rays will only detect old cysts that have calcified. Ultrasonography may enable the visualization of the echogenic scolex in viable cysts (Satya et al., 2016).

Imaging studies are the most helpful in establishing the diagnosis of ophthalmocysticercosis. High resolution ultrasonography (USG), computed tomography (CT) and magnetic resonance imaging (MRI) help in the detection of the orbital cyst. The clinical diagnosis of live intraocular cysticercosis is based on the morphology of the parasite as visualized with the ophthalmoscope or slit-lamp biomicroscope (Dhiman et al., 2017).

Neurocysticercosis

Currently, a combination of neuroimaging tools and immunodiagnosis is used to identify cysticerci in the SNC. CT and MRI are safe and precise techniques (providing data on the number, localization, stage of the lesions and inflammation status). However, as they are also expensive ways of diagnosing NCC, they are usually scarce in many impoverished endemic areas of the world. Routine hematological tests are of poor use and, to date, molecular tests are not sensitive enough to be directly applied for routine case assessment (García et al., 2020).

When neuroimaging is inconclusive, the diagnosis can be confirmed with serology. Antibody detection is more frequently used given its higher sensitivity. The assay of choice for antibody detection is the enzyme-linked immunoelectrotransfer blot (EITB) assay, using lentil lectin purified parasite glycoprotein antigens (LLGP), which is available through the CDC Parasitic Disease Reference Laboratory (García et al., 2018). EITB sensitivity is around 98% for patients with two or more live parasites in the nervous system. However, the sensitivity is low (50–60%) in patients with only one intracranial cysticercus. The sensitivity is, in turn, higher in serum than in CSF (100% vs. 90%) (García et al., 2014). EITB specificity seems to be 100%, although pigs infected with *T. asiaticus* showed positive bands when tested with the EITB assay (Pilcher et al., 1991). The antibody detection in CSF by ELISAs in patients with more than one viable cysticercus is 89% sensitive and 93% specific. ELISAs are used when EITB is not available (García et al., 2014).

The detection of parasite antigens confirms the presence of viable parasites. Circulating antigens are only present as long as the infection is active. That is why the detection of antigens by ELISA with monoclonal antibodies in serum (the duration of antigens in CSF is unknown) is used to monitor the effectiveness of treatment or surgery (García et al., 2014).

Considering that tuberculosis and NCC show similar clinical and radiological features, a panel of diagnostic criteria for NCC was elaborated by Del Brutto et al. (2001), which has recently been updated by García et al. (2020). These diagnostic criteria are organized into absolute, neuroimaging, and clinical/exposure criteria. Likewise, proper interpretation of these criteria allows two degrees of diagnostic certainty, definitive and probable. These criteria have been widely used for the diagnosis of NCC in both hospital and field settings and have proven useful in areas of endemicity and non-endemicity.

Treatment

Taeniasis

Two drugs are the most effective against the three species of human *Taenia*, niclosamide and praziquantel. Niclosamide has little absorption, and therefore, no effect on NCC. However, praziquantel is well absorbed after oral administration and it is active not only against the adult stages of *Taenia* spp. but also against the larval stages. In the case of human taeniasis caused by *T. solium*, the patient could probably be infected by the adult stage as well as by the cysticercus. Therefore, to avoid that possible previously silent brain cysts can trigger seizures or other neurological symptoms as a consequence of the treatment with praziquantel (Flisser et al., 1993), niclosamide is recommended in *T. solium* taeniasis cases.

According to the systematic review conducted by Haby et al. (2020), the treatment with niclosamide 2 g for adults, praziquantel also in a single oral dose of 10 mg and triple-dose albendazole 400 mg, seem to be effective as taenicides in mass chemotherapy for *T. solium* taeniasis. However, White et al. (2020) are critical of the systematic review elaborated by Haby et al. (2020), since with respect to the analysis of efficacy, the authors did not account for differences in the methods used to ascertain the outcomes in the studies analyzed.

Neurological side effects in *T. solium* carriers are a potential danger in albendazole treatment that, like praziquantel, also crosses the blood-brain barrier (Sotelo and Jung, 1998).

Cysticercosis

Cysticercosis outside of the central nervous system and the eye is usually asymptomatic and does not require therapy. Untreated intraocular cysticercosis incites severe ocular inflammation, more so when the cyst dies. Anthelmintic therapy can lead, in turn, to severe inflammation in the event of a live cyst degenerating, hence, surgery is the treatment of choice.

In NCC cases, a single therapeutic approach does not exist. Depending on the viability, size and location of the cysts as well as the severity of the host immune response, a rational treatment has to be planned (García and Del Brutto, 2000). The treatment of NCC involves (Nash, 2003; Quintana, 2013): (i) prevention and health monitoring; (ii) anthelmintic drugs, which induce the death of

the larva and tapeworm; (iii) corticosteroids and other agents, which reduce or prevent the inflammatory phenomena related to the involution of the cyst, either spontaneous or induced; (iv) antiepileptic drugs, which reduce the frequency of or suppress seizures; (v) osmotic diuretics to treat increased intracranial pressure; and (vi) surgical procedures to treat increased intracranial pressure, hydrocephalus, and the mass effect of some lesions.

Related to the use of anthelmintic treatment in NCC, unfortunately, the efficacy of the two available cysticidal drugs, albendazole and praziquantel, is suboptimal, with cure rates between 40% and 50% at the doses usually recommended (Nash et al., 2013). The main point of the debate on the treatment of NCC is centered on whether the destruction of parasites by the antiparasitic drugs has clinical benefits to patients. There are arguments in favor (disappearance of the cysts, better clinical evolution of the treated patients, less severe cases), as well as against (antiparasitic treatment can cause severe and unnecessary brain inflammation or stroke which can be fatal, NCC becomes symptomatic only when the parasite naturally dies years after) (García et al., 2017). In 2002, a relative consensus was adopted among the specialists involved in the disease, and guidelines for the use of antiparasitic treatment in NCC were published (García et al., 2002).

Surgery is reserved for selected patients with NCC and plays a minor role in the management of the disease. The commonest indication is for the excision of intraventricular cysts, with endoscopy surgery being the procedure of choice as it is minimally invasive (Rajshekhar, 2010).

Control

Transmission of taeniasis has been largely eliminated in industrialized countries by improving sanitation and meat inspection. The intervention measures in the three *Taenia* species to interrupt the life cycle can be targeted at human level (tapeworm carriers as the infective source of infection of human, porcine and cattle cysticercosis), and at pig and cattle level (infected pigs and cattle as reservoirs of human taeniasis). Most of the control interventions target *T. solium* in order to prevent human NCC.

At human level

Ignorance is a major obstacle for the effective control of whatever disease. Even small changes in the behavior of people living in endemic areas by means of public education can affect parasite transmissions. In this sense, Johansen et al. (2014) developed an inexpensive, locally-adaptable, and implementable computer-based education tool, "The Vicious Worm," to improve the knowledge concerning *T. solium*.

By not eating raw or poorly cooked pork (*T. solium*, *T. asiaticus*) or beef (*T. saginata*), the likelihood that a person becomes infected is considerably reduced. Meat should be cooked at a temperature of between 60 °C and 65 °C, or until it loses its pink color, to ensure that cysts are killed (Okello and Thomas, 2017).

Improvements in personal sanitation (personal hygiene, washing hands after defecation) and safe disposal of feces (avoiding open defecation) could prevent human and porcine/bovine cysticercosis.

A limiting factor of the widespread application of health education is, on one hand, the high cost of such programs (Pawlowski et al., 2005), which also impacts the sustainability of this measure of this control measure. On the other hand, in cases in which health education has been included together with other intervention measures against *T. solium*, education appears to have had a limited impact (Lightowers, 2013; Thomas, 2015).

Preventive chemotherapy is defined as the use of anthelmintic drugs, either alone or in combination, as a public health tool against helminth infections (WHO, 2006). Treatment of *Taenia* spp. carriers can be implemented in three ways (Gabrielli et al., 2011): mass drug administration (MDA) (the whole population is treated), targeted chemotherapy (only specific risk groups are treated), and selective chemotherapy (only patients, according to clinical status, are treated). Both, MDA and selective chemotherapy have been recommended for the control of *T. solium* and some evidence is available on their relative efficacy and cost-effectiveness.

The multiple control initiatives implemented in Ecuador, Guatemala, Mexico, and China were reviewed by Thomas (2015), concluding that (sic). "Despite inconclusive evidence on the efficacy and cost-effectiveness of identification and treatment of taeniasis as a control strategy, the epidemiological basis of removing carriers from the population is undeniable. We would strongly recommend that all in-contacts of NCC cases are treated (2 g niclosamide for safety) as standard (Lian F. Thomas and Andrea Winkler)".

At porcine/bovine level

A key point in the propagation of the *Taenia* spp. lifecycle is the contact between pigs/cattle and human fecal material containing infective eggs. Hygiene measures such as best practices in animal husbandry and a correct management of sewage sludge and wastewater contribute to the prevention of the intermediate host becoming infected.

To prevent infection, chemoprophylaxis in pigs has been widely suggested as a control strategy. Besides, several vaccines against *T. solium* pig cysticercosis have been developed, of which two have progressed a great deal and have shown a high degree of potential for use in control strategies, namely SP3Vac and TSOL18 (Cysvax® produced by India Immunological Limited). Vaccination of

cattle against *T. saginata* with the TSA9/TSA18 vaccine has been attempted with some success. However, it does not seem that this vaccine is going to be commercialized any time soon (Thomas, 2015).

Once infected, porcine cysticercosis can be treated with a series of anthelmintics (Lightowlers, 2013; Thomas, 2015) of which oxfendazole (one single dose of 30 mg/kg) has demonstrated the best efficacy with a rapid reduction in cyst viability with 50% of cysts found to be nonviable at 1 week post-treatment and after 12 weeks all muscle cysts appear to be nonviable. Bovine cysticercosis also responds to anthelmintic treatment with praziquantel, and protection against reinfection appears to last for at least 12 weeks. Despite its efficacy, praziquantel has not yet been formulated for cattle and is, therefore, not commercially available as a control measure for *T. saginata* (Okello and Thomas, 2017).

Once dead, post-mortem detection of cysticerci in pigs and cattle by means of visual inspection of the carcasses is fundamental to prevent human taeniasis. However, meat inspection lacks sensitivity, especially in cases of low cost burden. In addition, in many *T. solium* endemic low income countries infected pigs are diagnosed ante-mortem (tongue inspection) and sold in clandestine markets, thus escaping the condemnation of carcasses (Murrell, 2005).

Cold treatment has been proven to kill the cysticerci of *T. solium* and *T. saginata*, within 6–10 days at temperatures below -10°C and at -24°C in just 24 h (Sotelo et al., 1986; Hilwig et al., 1978). In addition to freezing, gamma-radiation, cooking and salt pickling have been shown to successfully reduce the viability of cysticerci.

Combining methods in the one health approach

Available data suggests that choosing a single approach to control human *Taenia* is not sufficient. The three *Taenia* species cause zoonotic diseases, in which not only humans but also animals are involved. Therefore, to tackle the problem, strategies that target both, the human and animal hosts, should be adopted (Okello and Thomas, 2017).

In this sense, WHO is promoting prevention and control of *T. solium* infection through animals with the One Health approach (<https://www.who.int/activities/promoting-prevention-and-control-of-taenia-solium-infection-through-animals-with-the-one-health-approach>). Specific control measures in the pig population include the vaccination of pigs with the TSOL18 vaccine and the treatment with oxfendazole.

Multiple control initiatives can be found in the literature with different results. One successful example is Peru: a large integrated program combining human and porcine mass chemotherapy, pig vaccination, and coproantigen detection-based case confirmation over a one-year period has proven effective in achieving focal elimination of *T. solium* transmission in a large area on the northern coast of the country (García et al., 2016). Likewise, more recently, the integrated interventions in humans and pigs carried out in a 2-year study in Zambia (Africa) (CYSTSTOP), eliminated viable infection in pigs and significantly reduced the prevalence of taeniasis caused by *T. solium* in the intervened villages (Gabriel et al., 2020).

Future perspectives

Taenia solium: The 2012 WHO roadmap for *T. solium* control and elimination by 2015 or 2020, depending on the countries, has not been met, although notable progress has been made (De Coster et al., 2018). *T. solium* has been included in the consultation process for the new 2030 goals proposed for priority NTDs (CystiTeam Group for Epidemiology and Modelling of *Taenia solium* Taeniasis/Cysticercosis, 2019). According to Dixon et al. (2020), the 2030 target is technically feasible with the current intervention options and tools with the implementation of computational transmission models such as cystiSim (Braae et al., 2016) and EPICYST (Winskill et al., 2017). However, current tools, like diagnostic methods or necropsy of pigs to measure the infection, present many limitations to effectively achieve the target. Existing *T. solium* models can be improved through collaboration between modeling groups, field epidemiologists, program stakeholders and policymakers, and used jointly to support the design, implementation and assessment of interventions in endemic countries (Dixon et al., 2020).

Taenia saginata: Since the eggs of *T. saginata* do not infect humans, NCC is not related to this species, and therefore, the human burden of disease related to this species is assessed as low, although no precise studies have been undertaken. In this sense, the FERG (WHO Foodborne Disease Burden Epidemiology Reference Group) report excluded *T. saginata* from their priority list (FERG, 2015). *T. saginata*, therefore, is mainly of economic interest in the cattle industry due to carcass condemnation. In this sense, *T. saginata* has recently been included in a risk-based surveillance for meat-borne parasites by means of a design tool called SURVTOOLS (Alban et al., 2020).

Taenia asiaticus: An international forum called *Taenia asiatica* Research Group was created in 2011 (TaRG international, [targint.net](http://taeniarsearchgroup.net)) to raise awareness of the existence of this third *Taenia* species, *T. asiaticus*, among veterinarians, health workers and researchers. TaRG is made up of scientists from countries of different continents with the aim of cooperating in the molecular identification of human and pig material (adult and larval stages) around the world. This cooperation is essential to definitely elucidate whether *T. asiaticus* is an exclusively Asian parasite or if it tends to be misdiagnosed around the world. Another gap in the pathogenicity of this species is to ascertain whether *T. asiaticus* is able to cause human cysticercosis (Galán-Puchades and Fuentes, 2004, 2013a,b). Currently, only molecular methods are able to identify *T. asiaticus* in humans and pigs, since morphology and immunology are useless, but unfortunately, although largely used in research, those methods are not employed in routine diagnosis.

Introduction

Human *Toxocara* spp. were first described by Wilder (1950). He identified a nematode larva of unknown species in eosinophilic granulomas within the enucleated eyes of children with suspected retinoblastoma, providing the first description of the condition currently known as ocular *larva migrans* (OLM). In 1952, Beaver and colleagues described *Toxocara* larvae in eosinophilic granulomas of the livers of young children with extreme eosinophilia, hepatomegaly, respiratory symptoms, anemia, and geophagia, and introduced the term visceral *larva migrans* (VLM) to describe this clinical syndrome (Beaver et al., 1952). They correctly classified, in histopathological sections of tissues obtained at biopsy, the causative agents as the larva of either *Toxocara canis* or *Toxocara cati*.

Systematics

Among the Nematodes belonging to the genus *Toxocara*, currently 26 species have been described.

The most frequently reported and wide spread zoonotic species is *T. canis*. Zoonotic infection with *T. cati* remains controversial and only a few infections, mostly in children with OLM, have been reported (Beaver et al., 1952; Fisher, 2003). Only a single-suspected case of human infection with *T. pteropodis* of bats has been reported and this species has yet to be confirmed as zoonotic. Of the non-zoonotic species *Toxocara vitulorum* of cattle is of major economic importance and there are other 13 species with minor economic impact (*Toxocara alienata*, *Toxocara apodemi*, *Toxocara genettae*, *Toxocara indica*, *Toxocara leonina*, *Toxocara mackerrasae*, *Toxocara malaysiensis*, *Toxocara paradoxura*, *Toxocara pearsei*, *Toxocara sprengi*, *Toxocara surkattae*, *Toxocara tanuki* and *Toxocara vajrasthira*). Further nine species have been reported only once and only in animals: *Toxocara canis*, *Toxocara cynonycteridis*, *Toxocara elephantis*, *Toxocara herpestum*, *Toxocara hippopotami*, *Toxocara lynx*, *Toxocara manzadiensis*, *Toxocara vincenti* and *Toxocara warren*.

Toxocara spp. have different definitive host species, such as canids, felids, civets, mongoose, cattle, raccoons, bats and rodents (Ziegler and Macpherson, 2019).

Canids and felids (puppies under 6 months of age and kittens between 2 and 6 months old, more frequently) are the definitive hosts of the only 2 species recognized as causal agents of human toxocariasis, *T. canis* and *T. cati*, respectively (Lightner et al., 1978; Roddie et al., 2008).

Epidemiology

T. canis and *T. cati* are ubiquitous parasites of dogs and cats, respectively, worldwide.

For both *T. canis* and *T. cati*, paratenic hosts can act as important reservoirs of infection for the circulation and maintenance of the parasites in the environment (Dubinsky et al., 1995).

Infection rates are defined by the presence of eggs in feces of dogs and cats contaminating the environment.

The remarkable fecundity of *Toxocara* spp. worms explains the high level of environment contamination with *Toxocara* eggs (Roddie et al., 2008; Amaral et al., 2010; Kłapeć and Borecka, 2012).

Female worms may produce up to 200,000 eggs per day. Eggs passed in the feces are not infective and must remain in the soil to become embryonated, then infective (Glickman and Schantz, 1981), depending on the soil type and environmental conditions such as humidity and temperature, and potentially remaining viable in the soil for several years posing an infection risk to humans (Overgaauw, 1997a; Mizgajska-Wiktor and Uga, 2006).

Table 1 lists the positivity rates deriving from the analysis of approximately 43,000 fecal samples, collected in different geographical areas of the World, in 40 Countries (Fakhri et al., 2018).

Humans acquire the infection as accidental hosts ingesting eggs of *Toxocara* spp. via contaminated hands or food (Overgaauw, 1997b).

Since humans are accidental hosts of *T. canis* and *T. cati* and do not develop patent infections, exposure must be estimated using seroprevalence studies, although these have many limitations (first of all the underestimation due to the low sensitivity of the methods used). Seroprevalence of *Toxocara* spp. varies widely worldwide (Rostami et al., 2019).

Seroprevalence surveys carried out in Western countries showed that the positivity rate was between 2% and 5% among apparently healthy adults from urban settlements, whereas it ranged from 14.2% to 37% in rural areas (Holland et al., 1995; Magnaval et al., 2001). When a tropical humid climate is combined with a poor socio-economic status, the transmission level of toxocarasis appears to be significantly higher, as the seroprevalence rate among children was found to be 47% in Salvador, Brazil (Mendonça et al., 2012), 63.2% in Bali (Chomel et al., 1993) and 86.8% in the Marshall Islands (Fu et al., 2014), respectively. The rate was shown to peak at 92.8% in teenagers and adults in La Réunion island (French Overseas Territories, Indian Ocean) (Magnaval et al., 1994).

There are several factors that have been associated with higher rates of infection with *Toxocara*:

- geophagia (common to find in neuropsychiatric conditions such as autism spectrum disorders) (Holland et al., 1995; Won et al., 2008; Pieroni et al., 2021);
- ingestions of raw vegetables or fruits grown in contaminated kitchen gardens /soil (Yoshikawa et al., 2008; Kłapeć and Borecka, 2012; Noh et al., 2012);

Table 1 Globally and regional environmental contamination by eggs of *Toxocara* spp., found in stool samples (in bold the extreme values) (Fakhri et al., 2018).

- ingestion of raw liver or other undercooked organs from an infected paratenic host (a host that is not required for the parasite life cycle but nonetheless can serve to maintain the life cycle) like rabbit, chicken, cattle, or swine, containing encapsulated larvae, see below (Nagakura et al., 1989; Lim, 2008; Yoshikawa et al., 2008; Kłapeć and Borecka, 2012; Noh et al., 2012; Yoshida et al., 2016);
- having a dog as a pet or close contact with pets or exposure to playgrounds and sandboxes contaminated by dog feces (Holland et al., 1995; Wolfe and Wright, 2003; Roddie et al., 2008; Hotez and Wilkins, 2009; Amaral et al., 2010; Keegan and Holland, 2010, 2013);
- younger age (Centers for Disease Control and Prevention, CDC, studies have shown that toxocariasis is predominantly a disease of children, typically those aged 2–7 years) (Holland et al., 1995; Centers for Disease Control and Prevention, 2011);
- male > female risk exposition (Holland et al., 1995; Won et al., 2008; Yoshida et al., 2016);
- low sanitation levels (Kroten et al., 2018);
- socio-economic status (this infection is more common in people living in poverty) (Hotez and Wilkins, 2009; Congdon and Lloyd, 2011);
- tropical regions (Azam et al., 2012) and rural areas (Holland et al., 1995; Magnaval et al., 2001);
- ethnicity (studies by the US CDC have found that, among all age groups, toxocariasis is more common in non-Hispanic blacks than in Mexican Americans and non-Hispanic whites) (Centers for Disease Control and Prevention, 2011; Congdon and Lloyd, 2011).

Toxocariasis is currently an important preventable zoonosis occurring worldwide (Won et al., 2008), even if, despite the high levels of seroprevalence that can be found in various geographical regions, it remains relatively unknown in public opinion and it is considered a neglected parasitic infection, that has been targeted by CDC for public health action.

Fig. 1 (1–11) summarizes *T. canis* and *T. cati* life cycle accomplish their life cycle in dogs and cats, respectively, with human acquiring the infection as accidental hosts (Fig. 1).

Fig. 1 The life cycle of *Toxocara* spp. (<https://www.cdc.gov/parasites/toxocariasis/biology.html>).

Adult worms reside in the small intestine of dogs or cats where females produce unembryonated eggs which are passed into the environment in the feces, 4–5 weeks after initial infection by *T. canis*, 8 weeks after initial infection by *T. cati* (Overgaauw, 1997a).

In the environment (1) (the numbers in parentheses are referred to those in Fig. 1), eggs embryonate and become infective within 3–6 weeks (2).

Following ingestion of infective eggs by younger dogs or cats (3), the eggs hatch and larvae (0.5 mm in length) penetrate the gut wall (4), enter the venous vessels and migrate via the liver to the lungs where they can pass the capillary blood vessel wall to reach the alveoli (Overgaauw, 1997a); from here, the larvae either migrate up to the trachea, oral pharynx where they are swallowed and returned to the small intestine to develop into adult worms, which then copulate and the females become gravid, producing eggs which will be excreted with feces (1), or undergo visceral migration (Glickman and Schantz, 1981).

Tracheal migration and the development of a patent infection are more common in young dogs (Greve, 1971); in contrast to the dog, tracheal migration and the development of a patent infection can remain high in older cats although it is still less frequent than in younger cats (O'Lorcain, 1994).

Where somatic migration occurs, the larvae do not develop into adult worms and they can remain in a state of arrested development in the tissues of the host for many years (Overgaauw, 1997a). This phenomenon offers two further possible ways of transmission of *T. canis* if the dog becomes pregnant: (a) the larvae can be mobilized from the tissues and migrate across the placenta infecting puppies in utero, leading to tracheal migration in the pup and eggs being shed in the feces 2–3 weeks after birth, or (b) they can migrate to the mammary glands and infect puppies during lactation in which case there is no tracheal migration and the larvae develop to adults in the intestines (Overgaauw, 1997a).

Infection during lactation is possible for *T. cati*, too (Coati et al., 2004), but there is no transplacental transmission.

Toxocara spp. can also be transmitted through ingestion of paratenic host organs. Eggs ingested by small non canine mammals (such as rabbits) can hatch and larvae can penetrate the gut wall with subsequent migration into various tissues where they encyst (7). The life cycle is completed when dogs or cats eat larvae encysted in the tissues of these paratenic hosts (8) and the larvae develop into egg-laying adult worms in the small intestine. It is probably a route of transmission more significant in cats than in dogs, given the predatory nature of cats.

Humans are accidental hosts who become infected by ingesting infective eggs in contaminated soil or food (9) or via ingestion of encysted larvae in the tissues of infected paratenic hosts (11), direct contact with infected puppies and kittens as sometimes pets carry embryonated eggs in their fur (see section on risk factors for human toxocariasis); following ingestion, the eggs hatch and larvae penetrate the intestinal wall and are carried by the circulation to a variety of tissues (liver, heart, lungs, brain, muscle, eyes) (11). The larvae do not undergo any further development in these sites, but the host inflammatory response against the migrating larvae can cause both mechanical and immunopathologic damage to tissues, which leads to local reactions that are the basis of clinical toxocariasis.

Immune response and pathogenesis

Disease severity depends not only on the number of larvae ingested but also on the degree of inflammation caused by the immune response directed against the excretory-secretory (ES) antigens of *Toxocara* spp. larvae (Fig. 2). These antigens are a mixture of glycoproteins, including a potent allergenic component named TBA-1 (Zibaei et al., 2019).

ES antigens stimulate CD4⁺ T helper-type 2 (Th2) lymphocytes (Maizels, 2013; Zibaei et al., 2019). *Toxocara* spp. infection also causes a concomitant reduction in the number of Th1 cells (Zibaei et al., 2019). It is worthy of note that Th2 cells were described for the first time in humans using lymphocytes from *Toxocara*-infected patients, stimulated with ES (Del Prete et al., 1991).

The Th2 responses are specially recognized by the production of the type 2 cytokines interleukins (IL) -4, IL-5, IL-9, IL-10 and IL-13, during infection and each one individually begins different immunological pathways. IL-4 induces B lymphocyte differentiation and antibody class-switching versus IgG1 subclass, with significant levels of IgE (Fillaux and Magnaval, 2013; Zibaei et al., 2019). IL-5 causes the differentiation of eosinophils, and their activation which leads to the production of superoxide anion and other damaging free radicals, major basic protein, etc. (Maizels, 2013; Zibaei et al., 2019).

Apart Th2 responses significant increase in IFN- γ levels have been found in VLM, as evidence of a complex cytokine response (Maizels, 2013).

The granulomatous inflammatory response, characterized by aggregates of eosinophils, neutrophils and monocytes, leads to the encapsulation of larvae and blocks their migration elsewhere (Kayes, 2006). Some larvae are able to escape the confines of these granulomas; indeed, serial sections of an entire granuloma may yield no evidence of the larva which initiated the response (Kayes, 2006).

The granulomatous inflammatory response and the raised antibody titer and eosinophilia appear incapable to control or eliminate *Toxocara* spp. larvae, which has given rise to the idea that the parasite is able to evade host immunity (Maizels et al., 2006). Studies have shown that *T. canis* larvae have a mucin-rich, highly labile surface coat which is loosely attached to the parasite epicuticle, and is shed when antibodies and/or eosinophils bind, allowing the parasite to escape (Maizels et al., 2006).

Toxocara spp. related immunopathological reactions have prompted researchers to investigate the association between *Toxocara* spp. infection and allergic asthma.

Certainly, patients with atopy may experience more severe toxocariasis or vice versa.

Fig. 2 Allergy and immune responses in toxocariasis.

Clinical manifestations

The degree of host damage and concomitant manifestation of clinical signs and symptoms are determined by the size of the inoculum, the location of the invading larvae and the host immune response (Pawlowski, 2001; Despommier, 2003).

Because the *Toxocara* seropositive population is much common than that with clinical toxocariasis, most patients are thought to be asymptomatic.

The most common characteristic of *Toxocara* spp. infection is chronic eosinophilia, while most of the clinical manifestations vary depending on the organs infected.

Nowadays, four different syndromes have been described: VLM, OLM, neurotoxocariasis (NT) and covert toxocariasis (CT) (Hamilton et al., 2014; Ma et al., 2018).

Visceral larva migrans

VLM occurs most commonly in young children and it is thought to be associated with a larger infectious dose and multi-systemic disorder, resulting in hepatitis and pneumonitis as the larvae migrate through the liver and lungs, respectively. Heavy infection may result in fever, anorexia, malaise, irritability, hepatomegaly, respiratory symptoms, pruritic urticaria-like cutaneous lesions, or other cutaneous manifestations such as transient rash, hypodermic nodules, chronic *prurigo*, miscellaneous eczema and vasculitis (Fig. 3A–C) (Gavignet et al., 2008), very often accompanied by eosinophilia.

Larvae frequently localize in the liver; hepatic manifestations may include hepatomegaly or nodular lesions (Laroia et al., 2012).

Pulmonary involvement may cause dyspnea, wheezing, and a chronic nonproductive cough in 20–80% of patients (Snyder, 1961; Huntley et al., 1965). Rales are common on physical examination.

Severe respiratory tract involvement is an uncommon complication of heavy infection.

Some studies have found a positive association between *Toxocara* spp. seropositivity and asthma in a large cohort of patients (over 11,000 adults with an age ranging between 18 and 65 years), suggesting a diminished lung function in the presence of *Toxocara* infection (Walsh, 2011).

Fig. 3 Cutaneous manifestations associated with toxocariasis. (A) urticaria; (B) chronic prurigo; (C) acquired disseminated eczema (Gavignet et al., 2008).

Granulomatous lesions, induced by the immune response to secreted larval antigens, both in the liver and lungs of infected patients can be mistaken for metastatic cancer (Anderson et al., 2006; Ota et al., 2009); the presence of eosinophilia may be helpful differentiating features.

Larvae can also migrate via the systemic blood circulation to muscles, the heart with myocarditis, pericarditis or Loeffler endocarditis potentially leading to heart failure or cardiac tamponade (Kuenzli et al., 2016), the eye, or the central nervous system (CNS) (Marx et al., 2007; Enko et al., 2009).

Ocular larva migrans

OLM involvement may occur as the sole manifestation; it often presents in individuals without antecedent history of symptomatic VLM (Good et al., 2004). OLM occurs most commonly among older children and adolescents (Hotez and Wilkins, 2009). In one review of ocular toxocariasis in the United States, the median patient age was 8.5 years (range 1–60 years) (Centers for Disease Control and Prevention, 2011).

The ocular lesion is due to larval localization in the eye and the granulomatous response around the larva. Common symptoms are unilateral visual impairment, causing failing vision and subsequent strabismus, leukocoria. The typical lesion is a whitish elevated granuloma. Occasionally, OLM may present as uveitis (often intermediate and posterior uveitis), papillitis, endophthalmitis, scleritis, or chronic endophthalmitis (Stewart et al., 2005). Ocular lesions may resemble retinoblastoma (Chuah et al., 2006). The most serious consequence of infection is invasion of the retina with granuloma formation in the periphery or posterior pole, leading to dragging of the retina and eventual retinal detachment, which can lead to blindness (Suh et al., 2006).

Neurotoxocariasis

Although humans are known to harbor *Toxocara* spp. larvae in the brain, as some studies describe the presence of larvae within granulomas in the CNS, discovered accidentally at autopsy when the patient had died from another cause (Dent et al., 1956; Hill et al., 1985; Nelson et al., 1990), possible clinical pictures of cerebral toxocariasis include eosinophilic meningo-encephalitis, space-occupying lesions, myelitis, and cerebral vasculitis (Deshayes et al., 2016; Dzikowiec et al., 2017). The degree of neurological symptoms is likely to depend on the number and location of the larvae in the brain, the immune response directed against them, and the resulting pathology (Despommier, 2003).

In a meta-analysis including 11 case-control studies and more than 4700 patients with toxocariasis, an association between epilepsy and *Toxocara* spp. seropositivity was observed (pooled odds ratio [OR] 1.69, 95% CI 1.42–2.01) (Luna et al., 2018).

Death due to CNS involvement has been described but is rare.

The pathogenetic connection between toxocariasis and impaired cognitive function is still under investigation (Richartz and Buchkremer, 2002).

Manifestations of the peripheral nervous system include radiculitis, affection of cranial nerves, or musculoskeletal involvement (Jabbour et al., 2011).

Covert toxocariasis

CT was first put forward by Taylor et al. (1987) to describe a series of mild, non-specific symptoms which did not fall within the categories of VLM or OLM yet were recognizable as *Toxocara* spp. infection.

Non-specific symptoms and signs to which CT refers include fever, abdominal pain, anorexia, nausea, vomiting, hepatomegaly, splenomegaly, cough, headache, lethargy, behavioral and/or sleep disturbances, skin symptoms, limb pains, and lymphadenitis associated with high titers of anti-*Toxocara* antibodies, with or without eosinophilia (Taylor et al., 1987).

CT mainly affects children beyond the toddler stage (Taylor et al., 1987).

A similar syndrome, probably variations of the same clinical entity, named “common toxocariasis” has been described by Glickman and Shofer (1987) among adults.

Such a variant of CT refers to a syndrome comprised of chronic weakness, shortness of breath, abdominal pain, rash, itch, urticarial and arthralgia, often with eosinophilia, high Ig E levels, and high titers of *Toxocara*-specific antibodies (Glickman and Shofer, 1987).

Diagnosis

The broad spectrum of clinical manifestations in toxocariasis (VLM, OLM, NT and CT) varies from asymptomatic to non-specific clinical signs which make it difficult to directly identify clinical cases of toxocariasis. High index of suspicion based on positive history for risk factors of toxocariasis and a set of symptoms and clinical signs induces clinicians to elaborate a diagnostic workup based on medical imaging techniques, hematological and biochemical assessment, serological tests, molecular methods, microscopic examination and histopathology to confirm diagnosis (Table 2).

Imaging techniques

Hepatic lesions may be observed with ultrasonography, computed tomography (CoT), and magnetic resonance imaging (MRI) (Jain et al., 1994; Zachariah et al., 1994; Laroia et al., 2012). Lesions in the liver appear as small multiple hypoechoic areas with abdominal US (Baldisserotto et al., 1999; Lim, 2008) and areas of low density with a CoT scan (Dupas et al., 1986; Lim, 2008), characteristically hyperintense lesions in T1 sequence without intravenous contrast (Bernardo-Cofiño et al., 2020) (Fig. 4).

Table 2 Diagnostic criteria for toxocariasis.

History	- Presence of risk factors of toxocariasis (e.g., geophagia, consumption of contaminated vegetables and raw or undercooked meat, exposure to dogs or playgrounds and sandboxes contaminated by dog feces, younger age, male gender, poverty, tropical and rural residence, ethnicity); - Presence of following symptoms: constitutional (fever, malaise, fatigue, etc.), cutaneous, gastrointestinal, respiratory, ocular, nervous system, cardiac, etc.
Physical examination	- Evidence of organ involvement (see clinical scenarios in VLM, OLM, NT, CT) supported by medical imaging techniques (e.g., US, CoT, MRI, ophthalmoscopy, bronchoscopy, echocardiography, etc.)
Routine laboratory tests	- Eosinophilia on peripheral blood and/or other specimens (e.g., bronchoalveolar lavage, cerebrospinal fluid.); - Hypergammaglobulinemia IgE and IgG; - Liver enzymes and function tests (plasma protein and cholinesterases, bilirubin, coagulation, etc.) alteration (possible if severe liver involvement)
Serological examination	- ELISA, western blot (need to confirm suspected cases)
Molecular diagnosis and microscopic examination and histopathology	- Not routinely performed
Differential diagnosis	- <i>Eosinophilia</i>: infectious diseases (helminths, such as strongyloidiasis, trichinellosis, filariasis, schistosomiasis, hookworm, ectoparasites, such as scabies and myiasis, protozoans, such as isosporiasis, sarcocystis myositis, fungi such as coccidiomycosis, allergic bronchopulmonary aspergillosis, histoplasmosis, viral such as HIV), allergic disorders (asthma, allergic rhinitis, atopic dermatitis), drug hypersensitivity (drug reaction with eosinophilia and systemic symptoms, eosinophilia-myalgia syndrome, interstitial nephritis, eosinophilic hepatitis), immunologic disorders (immunodeficiencies, such as hyper-IgE syndrome, autoimmune and idiopathic disorders, such as sarcoidosis, inflammatory bowel disease, IgG4 disease, other connective tissue disorders), eosinophilic disorders (idiopathic hypereosinophilic syndrome, eosinophilic granulomatosis with polyangiitis, formerly Churg-Strauss Syndrome, eosinophilic gastrointestinal disorders), neoplastic disorders (primary hypereosinophilic syndrome, acute or chronic eosinophilic leukemia, other myeloid neoplasms, such as chronic myeloid leukemia, systemic mastocytosis, lymphoid malignancies, such as B cell lymphoma, B or T leukemia/lymphoma, cutaneous T cell lymphoma/Sézary syndrome, solid tumor such as adenocarcinoma, squamous carcinoma), etc.; - <i>VLM</i>: strongyloidiasis, schistosomiasis, capillariasis, ascariasis, echinococcosis, allergic bronchopulmonary aspergillosis, cancer and metastatic cancer; - <i>OLM</i>: retinoblastoma, toxoplasmosis, tuberculosis; - <i>NT</i>: gnathostomiasis, toxoplasmosis, tuberculosis, cancer and metastatic cancer

Fig. 4 Liver lesion due to *Toxocara* infection in MRI: a characteristically hyperintense lesion in a T1 sequence without intravenous contrast (Bernardo-Cofiño et al., 2020).

Pulmonary involvement in VLM appear on chest radiograph as bilateral peribronchial infiltration; parenchymal infiltrates can also occur (Snyder, 1961; Huntley et al., 1965; Ribeiro and Fischer, 2002) (Fig. 5A).

CoT may demonstrate multifocal subpleural nodules with halo or ground-glass opacities and ill-defined margins (Ribeiro and Fischer, 2002; Sakai et al., 2006) (Fig. 5B).

In one review of radiographic changes associated with pulmonary VLM, four patterns were observed: ground-glass opacities, solid nodules, consolidation, and linear opacities; lower lung involvement was predominant (Lee et al., 2015).

Globally radiographic techniques demonstrate abnormalities in $\geq 40\%$ of patients with symptomatic illness.

Ophthalmoscopy, ocular US and CoT has been used as diagnostic techniques for the evaluation of patients with ocular toxocariasis (Liu et al., 2017). The *fundus oculi* typical lesion is a whitish elevated granuloma (Molina et al., 2019) (Fig. 6).

CoT and MRI can help to evaluate CNS involvement, revealing granulomas appearing on CoT as hypodense lesions (Fig. 7A) and on MRI as hyper-intense lesions on T2-weighted images (Fig. 7B), primarily located cortically or subcortically in brain areas (Ruttinger and Hadidi, 1991; Jabbour et al., 2011; Abir et al., 2017).

Laboratory tests

Peripheral blood eosinophilia is the most important finding; eosinophilia occurs in more than 30% of cases of VLM (Rubinsky-Elefant et al., 2010), however, it may be absent in patients with OLM or CT, presumably because of the low larval burden (Pawlowski, 2001). Eosinophilia may also be absent in patients with long-standing infection and in those with cutaneous symptoms only (McGuinness and Leder, 2014).

NT patients often show eosinophilia not in the peripheral blood but in the cerebrospinal fluid (Jabbour et al., 2011).

Pulmonary involvement may result in eosinophilia, detectable in bronchoalveolar lavage fluid (Roig et al., 1992).

An eosinophilic granulomatous hepatitis may develop, leading to abnormalities in liver function tests including elevated transaminases and/or alkaline phosphatase.

Patients with toxocariasis have often hypergammaglobulinemia with a marked increase in serum levels of total IgE and IgG.

Serological examination

Serodiagnostic tests should always be performed using at least two consecutive serum samples taken approximately 2 weeks apart.

The most commonly used serological tests for confirming toxocariasis are an indirect enzyme linked immunosorbent assay (ELISA) and western blot (WB) based on *Toxocara* ES antigens of the third-stage larvae (MagnaVal et al., 2001; Fillaux and MagnaVal, 2013; Yoshida et al., 2016).

This test cannot differentiate between *T. canis* and *T. cati* infections.

The reliability varies by time of infection and clinical presentation.

The sensitivity of the *Toxocara* ES-based ELISA for the detection of IgG and diagnosis of VLM has been estimated to be 91%, with a specificity of 86% (Jacquier et al., 1991).

Fig. 5 Toxocariasis chest images. (A) Radiograph of a three-year-old girl with toxocariasis; (B) CoT scan of the same 3-year-old girl with toxocariasis (Ribeiro and Fischer, 2002).

Fig. 6 Ocular toxocariasis: a white mass in the posterior pole of the right eye extending toward the macula suggestive of granuloma (Molina et al., 2019).

However, a positive ELISA result does not necessarily demonstrate the presence of active *Toxocara* infection or prove that clinical symptoms are attributable to toxocariasis, as IgG response elicited after *Toxocara* spp. infection may persist for many years (Cypess et al., 1977); the result must be interpreted in the setting of compatible clinical symptoms and epidemiologic exposure. However, a negative test can help to rule out VLM, although OLM and NT can occur with negative serology.

In OLM, the sensitivity of ELISA is considerably lower than for VLM, and even if it is positive an IgG or IgE titer is generally lower.

Fig. 7 Neurotoxocariasis: (A) brain CoT scan shows bilateral hypodense capsulo-lenticular lesions with focal nodular contrast enhancement (red arrows); (B) brain T2-weighted MRI shows the hyperintense lesions (red arrows). NB: The frontal lesions are post-traumatic sequelae (white and black arrows) (Abir et al., 2017).

ELISA with aqueous fluid (af) is therefore useful when OLM is suspected, and it is possible to compare the antibody levels between the serum and af; if the (level of specific IgG in af/serum level of specific IgG)/(total IgG in aqueous humor/total IgG in serum) is greater than 3.0, this can be considered diagnostic (de Visser et al., 2008). Negative serology can also occur with a positive af titer (Inchauspe et al., 2018).

However, for the diagnosis of OLM generally the findings on ophthalmologic examination are quite suggestive for etiology.

Cross-reactivity of the ELISA assay with other parasite antigens (e.g., ascariasis, anisakidosis, strongyloidiasis, trichinellosis, paragonimiasis, and fasciolosis) is common, and the test may remain positive for several years even following treatment (Elefant et al., 2006). In some settings, positive ELISA results can be confirmed by WB (MagnaVal et al., 1991), which has better sensitivity and specificity compared with ELISA (Roig et al., 1992), but it is also more expensive and labor intensive (MagnaVal et al., 1991; Fillaux and MagnaVal, 2013).

Other antibody isotypes, such as IgE, can be more specific and useful for identifying acute infection or progressive inflammation caused by toxocariasis and for monitoring therapy, but are less sensitive than IgG for the diagnosis (Elefant et al., 2006). Thus, more sensitive assays such as radioimmunoassay or fluoro-enzyme immunoassay are needed to detect *Toxocara*-specific IgE (MagnaVal et al., 2006). Unlike most other infections, IgM levels are present in both the acute and chronic phase of infection and are therefore not useful to distinguish between these two phases (Smith, 1993). Measuring the avidity of *Toxocara*-specific IgG antibodies may aid in distinguishing acute or chronic infections but not utilized on clinical practice (Dziemian et al., 2008; Rudzinska et al., 2017).

Molecular diagnosis

Methods for detecting circulating antigen are being developed (Rodríguez-Caballero et al., 2015).

Polymerase chain reaction-based methods for detecting *Toxocara* in clinical samples have been described but are not commercially available (Fogt-Wyrwas et al., 2007). Extraction of DNA is inconvenient for routine diagnosis of human infection since most patients have a very low worm burden and larvae are often not present in tissue samples. In an experimental murine model for toxocariasis, *Toxocara* larvae DNA was detected in bronchoalveolar lavage of infected animals using polymerase chain reaction assay (Pinelli et al., 2013). This finding indicated the possibility of using molecular tools and a less invasive method (bronchoalveolar lavage) for the direct diagnosis of toxocariasis particularly for patients with pulmonary disease. Future studies are needed to evaluate the sensitivity and specificity of these molecular diagnostic methods in human cases.

Microscopic examination and histopathology

Stool examinations are not applicable since the parasite does not complete a full life cycle involving the human gastrointestinal tract.

Definitive diagnosis of VLM may also be established via detection of larvae in biopsy tissue, which will show *Toxocara* larvae within eosinophilic granulomatous lesions. However, direct diagnosis of *Toxocara* infection through biopsies is not recommended since the larvae continuously migrate and biopsies are usually negative.

Furthermore, it remains difficult, or even impossible, to distinguish larvae of different *Toxocara* spp. as well as from larvae of other ascarid nematodes such as that of *Ascaris* spp. based only on their morphology (Nichols, 1956).

Treatment

Data on treatment approach are limited and often subject of debate due to the self-limiting nature of the disease, the lack of pathognomonic signs, and the possible development of allergic responses, particularly in critical sites such as the eye (Othman, 2012).

Thus, therapy varies according to symptoms and location of the larvae.

Most individuals with mild symptoms due to toxocariasis do not require anthelmintic therapy; symptoms are usually self-limited and resolve within a few weeks (Schantz and Glickman, 1978). Eosinophilia may resolve much more slowly over many months, likely due to ongoing antigenic stimulation from dead larvae. In the setting of protracted symptoms, the possibility of reinfection (such as from continued ingestion of contaminated soil) should be considered.

Treatment is usually recommended for individuals with moderate to severe symptoms due to VLM, significant peripheral blood eosinophilia (e.g., >1500/ μ L), inflammation foci in one or several organs (e.g., lungs, liver, heart, CNS) demonstrated in medical imaging, such as CoT, MRI, and US, active uveitis. Some are in favor of a treatment in the setting of moderate eosinophilia and positive serology even when only minimal symptoms are present, given risk of larval localization to the brain during the course of infection (Pawlowski, 2001; McGuinness and Leder, 2014).

Treatment consists of albendazole (ABZ) (400 mg orally with fatty meal twice daily for 5 days). In cases of severe respiratory, myocardial, or CNS involvement, OLM with sight-threatening ocular inflammation, concomitant prednisone (0.5–1 mg/kg/day) is warranted and ABZ treatment prolonged for 2 weeks or even up to 8 weeks (Pawlowski, 2001; Caumes, 2003; Kuenzli et al., 2016; Kakimoto et al., 2019; Hombu et al., 2019).

Optimal doses and duration of treatments are largely undefined.

The most frequent adverse events in the long-term treatment were liver dysfunction, which was reversible and well-tolerated in most cases (Hombu et al., 2019).

In complicated cases of OLM, surgical intervention may be warranted (Jee et al., 2016; Giuliani et al., 2011).

Mebendazole (MBZ) (100–200 mg orally twice daily for 5 days) is an alternative to ABZ (Magnaval, 1995), but ABZ is preferred (particularly in OLM and neurologic disease) since it crosses the blood-brain barrier. Ivermectin does not appear to be effective for toxocariasis as showed only moderate larvicidal activity in mice (Magnaval, 1998). Diethylcarbamazine (3–4 mg/kg/day for 21 days, starting at 25 mg/day for adults) has resulted effective in a small number of cases but with greater side effects than ABZ, for this it is rarely used.

Follow-up consists of monitoring clinical manifestations up to the resolution and of the eosinophil count, which usually decreases within 1 month of treatment (Magnaval et al., 2001). Serology is not useful for the limitation seen before.

Prognosis

Toxocariasis is generally a self-limited disease. The prognosis is good when adequately treated, except in some patients with severe VML, ocular or cerebral involvement.

Prevention and control

Toxocara spp. can be infective to a very wide range of accidental and paratenic hosts such as pigs, cattle, sheep, chickens and humans. Human toxocariasis is presumed to be acquired after the accidental ingestion of embryonated eggs or infective larva. No vaccines are available.

Prevention for minimizing the risk of infection is the best strategy.

Good hygiene practices, timely disposal of pet feces, and routine deworming of pets are important strategies for prevention of toxocariasis in humans (Centers for Disease Control and Prevention, 2011). Hand washing should be encouraged after contact with pets or areas at high risk for soil contamination, such as playgrounds and sandboxes (Centers for Disease Control and Prevention, 2011). Education regarding behaviors that increase risk for infection is also important, including geophagia and consumption of raw or undercooked meat (particularly liver).

Collaboration between veterinary and public health professionals plays a significant role in the control of toxocariasis.

Acknowledgment

The Au. are grateful to Dr. V. Rodriguez Fernandez for the preparation of Fig. 2.

Overview and background

Toxoplasma gondii is a coccidian parasite with a global distribution. The definitive host is the cat (and other felids) and all warm-blooded animals can act as intermediate hosts, including humans. Sexual reproduction (gametogony) takes place in the definitive host and oocysts are released in the environment, where they then sporulate to become infective. In intermediate hosts the cycle is extra-intestinal and results in the formation of tachyzoites and bradyzoites. Tachyzoites represent the invasive and proliferative stage and on entering a cell it multiplies asexually by endodyogeny. Bradyzoites within tissue cysts are the latent form.

T. gondii is a food-borne parasite causing toxoplasmosis, which can occur in both animals and humans. Infection in humans is asymptomatic in more than 80% of cases in Europe and North-America. Nevertheless, toxoplasmosis is life threatening if it occurs in immunocompromised subjects. Another aspect is congenital toxoplasmosis that may occur in pregnant women and the severity of the consequences depends on the stage of pregnancy when maternal infection occurs. Acute toxoplasmosis in developing fetuses may result in blindness, deformation, mental retardation or even death. Virulence and genotypes hardly influenced the clinical course of infection, in fact atypical genotypes are commonly associated to severe cases of congenital, ocular and disseminated toxoplasmosis also in healthy subjects.

The European Food Safety Authority (EFSA), in recent reports on zoonoses, highlighted that an increasing numbers of animals resulted infected with *T. gondii* in EU, high prevalence values have been detected in cats, cattle and dogs, as well as several other animal species, indicating the wide distribution of the parasite among different animal and wildlife species.

The main route of transmission is consumption of food and water contaminated with sporulated oocysts. However, infection through the ingestion of meat contaminated with tissue cysts is frequent. Finally, although less frequent, other food products contaminated with tachyzoites such as milk, may also pose a risk. Indeed, it has been reported that tachyzoites can resist gastric acidity for up to 30 minutes at a pH value of 4 (Koethe et al., 2017).

The importance of this parasite as a risk for human health was recently highlighted also by EFSA's opinion on modernization of meat inspection, where *T. gondii* was identified as a relevant hazard to be addressed in revised meat inspection systems for pigs, sheep, goats, farmed wild boar and farmed deer.

Taxonomical status

Phylum	Apicomplexa	Levine, 1980
Class	Sporozoa	Leukart, 1879
Subclass	Coccidiasina	Leukart, 1879
Order	Eimeriorina	Leger, 1911
Family	Toxoplasmatidae	Biocca, 1956
Genus	Toxoplasma	Nicolle and Manceaux, 1909
Species	Only one, <i>Toxoplasma gondii</i>	Named "gondii" after the African rodent (<i>Ctenodactylus gundl</i>) from which it was first isolated in the early 1900s. Nicolle and Manceaux, 1909

Toxoplasma gondii is a coccidian parasite, coccidia are among the most important parasites of animals and they were the first protozoa discovered (Dubey, 2010). The oocyst is the key stage of all coccidian and their classification was based on the structure of oocyst. Oocysts with four sporocysts, each with two sporozoites (total: eight sporozoites), are classified as *Eimeria*. Oocysts containing two sporocysts, each with four sporozoites, historically were classified as *Isospora* (Dubey et al., 2011). Unlike *Eimeria*, the life cycle of which has been known for many years, little was known of the complete life cycle of most *Isospora* species until 1970, when the life cycle of *T. gondii* was discovered and described. In that year, *T. gondii*, a parasite previously known as able to parasitize extra-intestinal tissues of virtually all warm-blooded hosts, was found to be an intestinal coccidium of cats and to have an isosporan-like oocyst (Dubey and Frenkel, 1972). This finding was a major breakthrough in medical and veterinary science and also led to the recognition of several new taxa of economically important *Toxoplasma*-like parasites (*Neospora*, *Sarcocystis*) and discovery of their cycles.

Historically, *T. gondii* originated probably as a coccidian parasite of cats with a fecal-oral cycle. With domestication, it adapted its transmission by several modes, including transmission by carnivorous, and transplacentally. There are three infectious stages of *T. gondii*: the tachyzoites, the bradyzoites, and oocysts, all linked in a complex life cycle.

Structure and life cycle

The tachyzoite is often crescent-shaped and is approximately the size of a red blood cell (2 μm $\times$ 6 μm). The anterior end of the tachyzoite is pointed (conoidal), and the posterior end is round. It has a pellicle (outer covering), several organelles including subpellicular microtubules, mitochondrion, smooth and rough endoplasmic reticula, a Golgi apparatus, apicoplast, ribosomes, micropore, and a well-defined nucleus which is usually situated toward the posterior end or in the central area of the cell.

T. gondii is able to penetrate various types of cells into innumerable hosts, indicating that the biochemical receptors recognized by the parasite for "attack" and therefore entry are quite common and widespread in most animal cells.

The penetration of the host's cell plasmalemma occurs in 26 s and the process involves two dependent Ca^{++} channels for the protrusion of the conoid and the secretion of the content of microneme and rhoptries for the formation of a moving junction. Once entered, the parasite is surrounded by a membrane derived from the plasmalemma which will then become the membrane of the parasitophorous vacuole where *T. gondii* is protected from host defense mechanisms. The tachyzoite multiplies asexually within the host cell by repeated divisions in which two progenies form within the parent parasite, consuming it. Tachyzoites continue to divide until the host cell is filled with parasites. The degree of replication is strictly dependent on the genotype and the host cell: more virulent genotypes replicate earlier and faster. The tachyzoites, despite the absence of eyelashes or flagella, move by wave and rotational movement. This is thanks to the activation of an actin-myosin system present at the level of the internal membrane.

After a few divisions, *T. gondii* forms tissue cysts and remains intracellular. Tissue cysts may vary in size: young ones may be small as 5 μm and contain only two bradyzoites, while older ones may contain thousands of organisms. Brain cysts usually reach 50–70 μm in size while those at the skeletal muscle level can reach 100 μm in diameter. The tissue cyst wall is elastic, thin (<0.5 μm), and may enclose hundreds of the crescent-shaped, slender *T. gondii* stage known as bradyzoites with dimensions of 5 $\times$ 8.5 μm . In the bradyzoites the nucleus is not central, as for the tachyzoites, but located in the back bottom. After inoculation (in experimental infections) the tissue cysts begin to form already after 3 days and constitute a fundamental part of the life cycle of *T. gondii*. Their location is dependent on the host, in fact, cysts have been found in lungs, liver, kidneys but they are more prevalent in muscular and neural tissues, including the brain, eye, skeletal, and cardiac muscle. Bradyzoites represent the cystic stage of the parasite. They live inside tissue cysts and replicate very slowly by endodyogeny. Inside the cyst they remain alive and vital and, when the host's immune defenses get down for any reason, the replication starts again in a more marked way until it determines the cyst rupture and the escape of infectious bradyzoites that can reach the circulatory stream and infect other cells and tissues after transformation into tachyzoites. Bradyzoites are slenderer and less susceptible to destruction by proteolytic enzymes than tachyzoites. After the ingestion of tissue cysts by cats, the tissue cyst wall is dissolved by proteolytic enzymes in the stomach and small intestine. The released bradyzoites penetrate the epithelial cells of the small intestine and initiate development of numerous generations of asexual and sexual cycles of *T. gondii*.

Toxoplasma gondii multiplies profusely in intestinal epithelial cells of cats (enteroepithelial cycle) and these stages are known as schizonts. Male and female gametes might derive from the merozoites generated by type D and E schizonts. The formation of

gametes occurs in the ileum, from 3 to 15 days after the inoculation or ingestion of tissue cysts, and we distinguish female and male gametes. With the two flagella the male gamete swims and enters the female gamete. After the female gamete is fertilized by the male gamete, the zygote formed will be surrounded by a wall which will contain the cytoplasm and the large central nucleus. At this point the epithelial cells break down, release the oocysts into the intestinal lumen which will then be eliminated in the environment with the feces. Shed oocysts are unsporulated and depending on external climatic conditions (temperature, humidity, oxygenation) need 1–5 days to sporulate and therefore become mature and infectious. The shape changes slightly becoming elliptical, the large nucleus of the zygote will divide giving birth to two sporoblasts with one nucleus each and a double lamina. As sporulation proceeds, the sporoblasts become longer, they become two sporocysts each containing four sporozoites formed by endoduo-geny, so that each oocyst contains eight sporozoites (Dubey, 2010).

Life cycle in the definitive host: The cat

Cats, both domestic and nearly all the species of felids, can shed *T. gondii* oocysts. Cats shed oocysts after ingesting any of the three infectious stages of *T. gondii*. Prepatent periods (time to the shedding of oocysts after initial infection) and frequency of oocyst shedding vary according to the stage of *T. gondii* ingested. They can go from 3 to 10 days after ingesting tissue cysts, and more than 18 days after ingesting oocysts, irrespective of the dose. The prepatent period after ingesting tachyzoites may vary. Fewer than 50% of cats shed oocysts after ingesting tachyzoites or oocysts, whereas nearly all cats shed oocysts after ingesting tissue cysts. *T. gondii* is adapted to be transmitted biologically by carnivorous cats and transmission by the oocysts is more efficient in non-feline hosts; bradyzoites are more infective to cats and oocysts are more infective to mice. After the ingestion of tissue cysts the tissue cyst wall is dissolved by proteolytic enzymes in the stomach and small intestine and initiates the development of numerous generations of *T. gondii*. Five morphologically distinct types of *T. gondii* develop in intestinal epithelial cells before gametogony begins. These asexual stages in the feline intestine are structurally distinct from tachyzoites that also develop in the lamina propria. The enteroepithelial stages (A-E gamonts) are formed in the intestinal epithelium and the development of types B-E schizonts in enterocytes. Tachyzoites occur exclusively within the lamina propria. Schizonts and gamonts develop exclusively in enterocytes. Types C, D, E multiply by schizogony; in this process the nucleus divides two or more times without cytoplasmic division. Before or simultaneous with the last nuclear division, merozoite formation is initiated near the center of the schizont. The merozoites eventually move towards the periphery of the schizont and the schizont plasmalemma invaginates around each merozoite forming the plasmalemma of the merozoite. The merozoites separate from the schizont at their posterior ends. The sexual cycle starts 2 days after ingestion of tissue cysts by the cat. The origin of gamonts has not been determined, but the merozoites released from schizont type D and E probably initiate gamete formation. Gamonts occur throughout the small intestine but most commonly in the ileum, 3–15 days after inoculation. They occur above the nucleus of the host epithelial cell near the tips of the villi of the small intestine. Female (macro) gamonts are subspherical and each contains a single centrally located nucleus and several PAS-positive granules. Mature male gamonts (micro) are ovoid to ellipsoidal in shape. During microgametogenesis, the nucleus of the microgamont divides and after several nuclear division, it migrates to the periphery of the gamont. Microgametes are biflagellate and contain a *perforatorium*; they use their flagella to swim to penetrate and fertilize mature macrogametes to form zygotes. After fertilization, an oocyst wall is formed around the parasite. Infected epithelial cells rupture and discharge oocyst into the intestinal lumen. Unsporulated oocysts are subspherical to spherical and are $10 \times 12 \mu\text{m}$ in diameter. Sporulation occurs in the environment, within 1–5 days depending upon aeration and temperature. Sporulated oocysts are subspherical to ellipsoidal and are $11 \times 13 \mu\text{m}$ in diameter. Each sporulated oocyst contains two ellipsoidal sporocysts measuring $6 \times 8 \mu\text{m}$. Each sporocyst contains four sporozoites. During sporulation the nucleus divides twice giving rise to four nuclei that are situated at the periphery of the zygote; at this stage, a second limiting membrane is formed. After the cytoplasm divides, two spherical sporoblasts are formed, each with two nuclei. As sporulation continues, the sporoblasts elongate and sporocysts are formed. Ultrastructurally, the sporozoite is similar to a tachyzoite except that there is an abundance of micronemes, rhoptries and amylopectin granules with a subterminal nucleus (Dubey, 2010).

Population structure of *Toxoplasma gondii*

The modern *T. gondii* was born in the Amazonian forest 1.5 million years ago (Bertranpetit et al., 2017).

The parasite is characterized by a clonal population structure and the genotypes are historically divided into types I, II, III. This distinction was originally made based on the different virulence patterns observed in mice. Despite the presence of a sexual stage in the life cycle of the parasite and a worldwide distribution, the population structure, in isolates genotyped and sequenced in United States and Europe, appears highly clonal with low genetic diversity. However, multi-locus and multi-chromosome genotyping of isolates from other continents have revealed a much more complex population structure. The majority of isolates in South America, Africa or Asia do not fit into the three major lineages and they are also considered the more virulent ones, responsible of important outbreaks and severe cases of ocular toxoplasmosis in humans (Carme et al., 2009; de-la-Torre et al., 2013).

Genotypes

Several molecular techniques including polymerase chain reaction, restriction fragment length polymorphism analysis (PCR-RFLP) (Su et al. 2006, 2010), microsatellite DNA analysis (MS) (Ajzenberg et al., 2010), multilocus DNA sequence typing of introns

(MLST) (Khan et al., 2011) and Whole Genome Sequencing have been used to study the genetic makeup of *T. gondii* isolates. PCR-RFLP genotyping is a relatively inexpensive, not needing sophisticated equipment technique, based on the analysis of 10 markers distributed over 8 chromosomes and one apicoplastic marker (Su et al., 2006). Microsatellite (MS) markers on the other side are more polymorphic and in this way more helpful to trace outbreaks and recent events of the evolutionary history of living organisms. The most recent and used technique is based on analysis of 15 MS markers distributed over 11 different chromosomes (Ajzenberg et al., 2010). With MLST it is possible to study the nucleotide sequences of several loci coding for housekeeping genes.

Up to now, 16 different haplogroups originating from 6 ancestral populations or clades have been described (including the initially 3 lineage I, II, III), based on DNA sequence typing and Whole Genome Sequencing. They are not completely homogeneous, in fact some isolates are defined as “atypical” for the presence of unique polymorphisms which cannot be clustered into one of the 16 haplogroups (Su et al., 2012; Lorenzi et al., 2016).

There is currently no precise nomenclature for *T. gondii* genotypes. Conventional designation defined type I, II, III and lumped together all the others as atypical or exotic. The subsequently identified major genotypes were added to the list including Type *BrI*, *BrII*, *BrIII* and *BrIV*, Type 12, *Africa 1* and *Chinese 1* (Pena et al., 2008; Mercier et al., 2010; Chen et al., 2011; Khan et al., 2011). However, this scheme of genotype designation is complicated to define the hundreds of genotypes identified by the multilocus PCR-RFLP method. To overcome this cumbersome designation, a scheme has been adopted in which each genotype is designated as a “ToxoDB PCR-RFLP genotype” followed by a specific numeral. The 10 most frequently identified are, in order, genotypes #2, #3, #1, #5, #4, #9, #6, #7, #8 and #10. Genotypes #1 and #3 differ only at the Apico locus, together compose the conventional Type II lineage. Genotype #1 is also referred to Type II clonal, whereas #3 as Type II variant. Genotype #2 is also known as Type III while genotypes #4 and #5, which differ only at the SAG1 locus, are collectively known as Type 12. Different studies reported that genotype #1, #2 and #3 (Type II clonal, Type III and Type II variant) are identified worldwide. These three genotypes are highly prevalent in Europe. Genotypes #1, #2, #3, #4 and #5 dominate in North America. Genotypes #2 and #3 (Types III and II variant) dominate in Africa, and genotypes #9 and #10 (*Chinese 1* and Type I) are prevalent in East Asia (Lorenzi et al., 2016).

Genotypes and their geographic distribution

From Northern to Southern Europe the population structure of *T. gondii* is highly clonal, with a predominance of strains belonging to the type II lineage. Type II and III predominate in Europe and atypical strains have been rarely isolated. In North America the population structure is very similar to that one described for Europe, but also a fourth clonal lineage (haplogroup 12) and atypical strains isolated both from domestic and wild animals showed an important prevalence (Dubey et al., 2011). A high level of diversity for *T. gondii* was recorded in Central and South America; in Brazil in particular numerous studies have highlighted the presence of atypical and new strains isolated from animals and also from humans with acute toxoplasmosis. Eighty-eight genotypes (defined with 11 genetic PCR-RFLP markers) have already been identified in Brazil, and new genotypes are continuously being identified in different animal species (Pena et al., 2011). The high level of genetic diversity was recorded in many species in the Amazonian area (Ajzenberg et al., 2004) and prevalence, incidence, severity of acquired and congenital ocular toxoplasmosis (OT) in some areas of Brazil, Colombia, and Argentina are considerably higher than anywhere else (de-la-Torre et al., 2008; Rudzinski et al., 2016).

Looking at African countries less information are available and most samples identified and genotyped (118/141) were from Egypt. Overall, genotype #3 and #2 are the two dominant types. Genotype #6, known as *Africa 1* microsatellite marker, and *Africa 3* were identified in Western and Central Africa and in Gabon, respectively (Mercier et al., 2010). The limited data that are available from sampling in Western Africa seem to suggest a high level of diversity, with a relatively low frequency of common genotypes (Shwab et al., 2014).

In Asia, there also appears to be a high degree of genetic uniformity. Genotype #9 (*Chinese 1*) is by far the most commonly found, and it is present in China, Vietnam and Sri Lanka, indicating a widespread distribution in Eastern Asia. Genotype #10 (Type I) is also common in China, unlike in most other countries. Genotypes #4, #18 and #20 have relatively high frequencies in Asia together with ToxoDB#1 and #3 (Type II and II variant) and #2 (Type III). Genotype #20 has been identified in a wide range of areas, from Sri Lanka in south Asia to Egypt in North Africa. Thus far, most of the sampling from Asia has been from the more populous eastern regions (Shwab et al., 2014).

Genotypes and virulence

Experimental virulence is defined by the mouse reaction after the inoculation of the parasite intraperitoneally. Type I isolates are highly virulent, leading to the death of mice in less than 10 days after the inoculation of less than 10 tachyzoites, while type II and III are considered avirulent strains, allowing survival after the inoculation of $>10^3$ tachyzoites. Also genotypes with a majority of type I alleles are usually more virulent (Mercier et al., 2010). The virulent strains display several characteristics that may explain the rapid dissemination and virulence. Type I strains are more rapid in destroying a cell monolayer than type II or III because they multiply rapidly and show a lower rate of tachyzoite-to-bradyzoite interconversion (Saeij et al., 2006).

In vivo infection with type I strains display a higher ability to penetrate the epithelia, lamina propria and submucosa (Barragan and Sibley, 2002).

It has been demonstrated that the rhoptry protein family, in particular the association between ROP5/ROP18, plays a role in the infection process. This allele association is always present in virulent strains and the deletion of ROP18 made the strains completely avirulent (Jensen et al., 2015).

As already reported, atypical strains mainly diffused in south America are responsible of serious clinical manifestations in humans. For example, many cases of multivisceral toxoplasmosis, commonly called "Amazonian toxoplasmosis," in immunocompetent people have been reported in French Guiana caused by highly pathogenic strains of the parasite from the wild (Carme et al., 2002). Similarly, in South America, in particular in Brazil, Colombia and northern Argentina, there is a high prevalence of severe ocular forms, representing a significant public health problem (de-la-Torre et al., 2013; Rudzinski et al., 2016). Because South America is also the hotspot of *T. gondii*'s genetic diversity, it has been hypothesized that severe forms of toxoplasmosis may be the consequence of poor adaptation of the human host to the unusual diversity of strains in this part of the world, resulting in impaired immune response and, thus, a more aggressive disease (Khan et al., 2006; Gilbert et al., 2008a). Also in North America, an association between the atypical strains and the incidence of severe ocular and systemic disease in immunocompetent patients has been recently found (Pomares et al., 2018).

Virulence factors of *Toxoplasma gondii* and host-parasite relationship

Virulence loci

During invasion of host cells, secretory organelles known as rhoptries discharge their contents into the host cell, making these primary candidates for modulating host signaling (Hakansson et al., 2001). ROP18 is an active serine/threonine (S/T) protein kinase that is secreted into the host cell where it decorates the surface of the parasitophorous vacuole membrane (PVM). It is a polymorphic protein and it was identified as a major factor that contributed to strain-specific differences in virulence (Taylor et al., 2006; Saeij et al., 2006). Transgenic expression of ROP18 from type I or type II strains in the type III background greatly enhanced virulence confirming that this locus was responsible for the observed differences in virulence between strains. The role of ROP16 in altering host gene transcription was initially identified by analyzing the differences in host gene expression induced by different parasite strains. These studies led to a focus on genes involved in IL-4 and IL-6 responses and implicated changes in the activity of the transcription factors STAT3 and STAT6 (Saeij et al., 2007). Although all three strains initially induce STAT3 and STAT6 activity, only the type I or III strains (which share the same ROP16 variant, ROP16I/III) sustain this response. Prolonged STAT3/6 activation by ROP16I/III down-regulates the induction of IL-12, thus limiting the protective TH1 cytokine responses (Saeij et al., 2007), which might lead to less inflammation, reduced pathology and also enhanced parasite survival.

Genetic studies show that the pseudokinase ROP5 is essential for acute virulence. ROP5 in fact is an inactive member of protein kinase family that controls virulence by blocking IFN- γ mediated clearance in activated macrophages. It is able to regulate the active protein kinase ROP18, which normally prevents clearance of the parasite in interferon-activated macrophages phosphorylating host immunity related GTPases (IRGs). Additionally, ROP5 has other functions indicating that it plays a general role in governing virulence factors that block immunity (Behnke et al., 2012, 2015).

Another virulence factor that stimulates a high production of IL-12, is a dense granule protein named GRA15. The molecular mechanism of GRA15 function is uncertain (Rosowski et al., 2011) but deletion of GRA15 in the type II strain ME49 prevents nuclear translocation of NF κ B and consequently the release of IL-12. This was demonstrated in particular for Type II GRA15 and not for Type I and III. The activation of NF κ B pathway by type II GRA15 results in high levels of IL-12 production, enhancing the classical activation pathway in cells infected by type II parasites. High production levels of IL-12 are also modulated by ROP16 since the allele expressed in type II strains is incapable of sustained phosphorylation of STAT3, and the down-regulation of the IL-12 induction.

Mechanism of cell invasion

Toxoplasma gondii usually parasitizes the host, definitive and intermediate, without producing clinical disease. Only rarely it produces severe clinical manifestations. The bradyzoites from the tissue cysts or sporozoites from the oocyst penetrate intestinal epithelial cells and multiply in the intestine as tachyzoites within 24 h of infection. The parasite may spread first to mesenteric lymph nodes and then to distant organs by invasion of lymphatic system and blood, and can multiply in virtually any cell in the body. All extracellular forms of the parasite are directly affected by antibody but intracellular forms are not. In fact, immunity does not eradicate infection and tissue cysts can persist for several years after acute infection, potentially for all the life of the subject. Whether bradyzoites can form new tissue cysts directly without transforming into tachyzoites is not known. It has been proposed that tissue cysts may break during the life of the host and the release of bradyzoites may induce their own destruction by the host's immune responses or alternatively, new tissue cysts may be formed.

In immunocompromised patients a rupture of a tissue cyst may result in transformation of bradyzoites into tachyzoites and renewed multiplication. This may lead to serious clinical complications till the death of the patient unless treated.

Pathogenicity of *T. gondii* is determined by the virulence of the strain and the susceptibility of the host species. Certain strains of mice are more susceptible than others and the severity of infection in individual mice within the same strain may vary. Mice of any age are susceptible to clinical *T. gondii* infection. Instead, if adult rats do not become ill, young rats can die of toxoplasmosis. Adult dogs, like adult rats, are resistant, whereas puppies are fully susceptible to clinical toxoplasmosis. Certain species are genetically

resistant to clinical toxoplasmosis, cattle and horses, for example, are among the hosts more resistant to clinical toxoplasmosis, whereas certain marsupials and New World monkeys are highly susceptible to *T. gondii* infection (Dubey and Beattie, 1988).

The immune response to *Toxoplasma gondii*

Innate immune response is mainly supported by a cell-mediated response through the production of high levels of IL-12, interferon γ , and the intervention of the implementation of B lymphocytes and T lymphocytes CD4⁺ and CD8⁺, necessary to “observe” the reactivation of the cysts and for the development of a protective immune response against a possible reinfection (Hunter and Sibley, 2012; Yarovinsky, 2014).

Humoral response is also important as it leads to the synthesis of IgA, IgM, IgE and IgG antibodies that act by preventing the parasite from attacking the surface receptors of the cells, blocking the cell invasion process, activating the complement pathway and driving the opsonization of the parasite itself (Sayles et al., 2000).

Most laboratory studies have used type II strains (intermediate virulence), which has facilitated the study of the immune response in mice during the acute and chronic phases of infection. They have shown that control of *T. gondii* requires the early production of the pro-inflammatory cytokine IL-12, which stimulates natural killer (NK) and CD4⁺ and CD8⁺ T cells to release IFN- γ (Johnson, 1992; Khan et al., 1994).

The importance of IL-12 induction in early infection is evident from studies reporting that monocytes (Robben et al., 2004) CD8 α ⁺ dendritic cells (DCs) (Reis e Sousa et al., 1997), plasmacytoid DCs (Bierly et al., 2008), and neutrophils (Bliss et al., 2000) all contribute to the production of this activation signal. IL-12 is also essential for controlling parasite growth.

IFN- γ is the major mediator of resistance to *T. gondii* and is crucial for the activation of a variety of antimicrobial mechanisms in hematopoietic and non-hematopoietic cells that limit parasite replication (Suzuki et al., 1988), altering cell metabolism. This cytokine also stimulates professional phagocytes to produce reactive oxygen and nitrogen intermediates, which can lead to parasite damage and growth inhibition in macrophages. This pathway relies on IRGs that are induced by IFN- γ and contribute to clearance of *T. gondii* in multiple cell types (Taylor et al., 2006). Although innate immune responses to *T. gondii* have been examined in detail, how these processes lead to the stimulation of adaptive immunity, including the ability of DCs to access antigens for priming of CD4⁺ and CD8⁺ T cells, are less well understood. Moreover, infection of host cells is associated with reduced expression of major histocompatibility complex (MHC) molecules (Lüder et al., 1998). Despite these mechanisms of avoidance, infection with type II strains of *T. gondii* leads to the activation and expansion of DCs and a strong CD8⁺ T cell response, while infection with virulent type I strains induces a weaker response (Tait et al., 2010). Several prominent endogenous antigens that are presented on class I MHC molecules include the dense granule proteins GRA6 and GRA4, and the rhoptry protein ROP7 (Frickel et al., 2008). These antigens are polymorphic between strains, suggesting that they may be involved in strain-dependent evasion mechanisms that also influence adaptive immunity. The importance of highly immunogenic surface antigens (SAGs) and SAG-related surface antigen (SRS) in stimulating the adaptive immune response have been also highlighted (Lekutis et al., 2001).

Alterations in host signaling and immune evasion

Many innate immune effectors are under the control of transcription factors that enhance or regulate the overall immune response to invading microorganisms. Infection of mammalian cells with *T. gondii* induces many changes in host cell gene transcription, including those genes involved in energy metabolism, immune responses and signaling (Blader et al., 2001). Infection with *T. gondii* inhibits host cell signaling pathways involved in protective immunity, for example, by blocking the transcription factors signal transducer and activator of transcription 1 (STAT1) (Lüder et al., 2001) and nuclear factor kappa-light-chain-enhancer of activated B cells (NF- κ B) (Butcher et al., 2001). Infection with *T. gondii* also upregulates anti-inflammatory pathways including those involving the suppressor of cytokine signaling protein (SOCS) 1 (Zimmermann et al., 2006), SOCS3 (Whitmarsh et al., 2011) and STAT3 (Butcher et al., 2011), potentially compromising host mechanisms of parasite control. Although IFN- γ promotes antimicrobial activities in many cell types, in macrophages it is not sufficient for the control of *T. gondii* and a second signal is required to fully activate killing. The best-characterized second signals that promote control of *T. gondii* in vitro are provided by TNF- α or signals through CD40 (Andrade et al., 2006; Reichmann et al., 2000), both of which utilize the NF- κ B signaling pathway. Notably, the activation of NF κ B by type II strains is associated with higher levels of IL-12 production (Robben et al., 2004), an effect that contributes to early control of infection.

Toxoplasmosis: Sources of infection

The majority of horizontal transmission in human is caused by the ingestion of tissue cysts in infected meat or by the ingestion of soil, water, or food contaminated with sporulated oocysts. The relative contribution of oocysts and tissue cysts to human infections is not well known, but experts assessed that 50% of infections are foodborne (EFSA BIOHAZ Panel (EFSA Panel on Biological Hazards), 2018).

Infection through tissue cysts

In Europe and in developed countries meat consumption was estimated to be responsible for about 50% of cases of infection (Scallan et al., 2011), while soil contact represented 6–17% of cases (Cook et al., 2000). Outbreaks due to the consumption of raw or undercooked meat have been described but they usually involve only a few patients (EFSA BIOHAZ Panel (EFSA Panel on Biological Hazards), 2018). In United States pork meat was estimated to be the main infection source for humans causing about 41% of foodborne human toxoplasmosis (Batz et al., 2012).

Regarding meatborne infections, it is known that the prevalence in livestock increases when the animals have outdoor access and increases with age. This underlines the importance of correct biohazard measures in farms and at the same time pose a question in relation to animal health. Organic and open access breeding assures best animal health conditions but the risk of infection increases.

Tissue cysts remain infectious in refrigerated carcasses (1 °C–6 °C) or minced meat for up to 3 weeks. However, the deep-freezing of meat at –12 °C or lower for at least 3 days is usually efficacious to kill cysts, although the effect may depend on the thickness of the piece of meat (Dubey, 1988). On the other side, tissue cysts are killed immediately when heated at 67 °C. Cooking for a prolonged period of time may be necessary under household conditions to achieve the temperature necessary to kill the cysts in all parts of the meat.

Infection through oocysts

A single cat may shed more than 100 million oocysts, which are non-sporulated. These need between 1 and 5 days to become infective for other hosts, depending on temperature, humidity and oxygenation, which explains why the direct contact with cats is not thought to be a major risk for human infection. Unsporulated oocysts lose the ability to sporulate and to become infective, after freezing at –6 °C for 7 days or after exposure to 37 °C for 1 day. Once sporulated they remain viable in a moist environment for more than a year. Under laboratory conditions, they resist at 4 °C for up to 54 months. They survive freezing at –10 °C for 106 days and heating at 35 °C and 40 °C for 32 days and 9 days, respectively. However, they are killed within 1–2 min by heating at 55–60 °C (when cooking vegetables for example). They are also high impermeable and very resistant to disinfectants (Dumètre and Dardé, 2003).

All these characteristics makes oocysts very resistant and durable; the reason why we can find them in water and in soil and from there they can reach vegetables and fruits and finally infect humans and intermediate hosts. Oocyst ingestion constitutes a significant proportion of *T. gondii* infections and the water-borne route of infection is one of the most common route of transmission of toxoplasmosis in human, mainly in countries with precarious infrastructure for water and sewage treatment. Lots of outbreaks have been described in Brazil for example with water or products implicated as the common source of exposure (Ferreira et al., 2018).

Infection through tachyzoites

Outside its host cell the tachyzoite is a fragile stage, and easily destroyed by digestive enzymes (10 min survival in pepsin-HCl). It is also very sensitive to environmental conditions and it usually dies rapidly outside the host. Therefore, tachyzoites are not thought to be very important for horizontal transmission from an epidemiological point of view. However, there is evidence that infected goats may release tachyzoites in milk and in rare cases subjects who drink unpasteurized goat's milk may acquire toxoplasmosis (Tenter et al., 2000). Similarly, also sheep can release tachyzoites with milk, as reported in Italy (Vismarra et al., 2017b). Tachyzoites are, however, responsible for congenital infection (mother-fetus) if the mother acquires primary toxoplasmosis during gestation. A real estimation of the incidence of congenital toxoplasmosis is difficult because in the majority of countries there are not mandatory monitoring programs, and neither pre- nor postnatal screening programs have been implemented in many countries. In France, where universal systematic screening of pregnant women exists from 1978 the incidence of seroconversion during pregnancy in 2010 was estimated at 2 per 1000 susceptible pregnant women but has decreased markedly during the last 30 years (Nogareda et al., 2014; Villena et al., 2010). The last report EFSA on zoonoses reported for 2017, 194 confirmed cases of congenital toxoplasmosis in the EU/EEA, with France accounting for 78.9% of all confirmed cases due to the active screening of pregnant women (EFSA and ECDC (European Food Safety Authority and European Centre for Disease Prevention and Control), 2019). In the United States, it is estimated that the incidence of congenital toxoplasmosis ranges from 500 to 5000 cases annually (Roberts and Frenkel, 1990). In Colombia a multicentric national screening of 15,000 newborns found an incidence of 1 case per 1000 newborns, with important regional variations related to mean annual rainfall (Gómez-Marín et al., 2011). One of the most important estimation about the global incidence of congenital toxoplasmosis was a meta-analysis published in 2013 by World Health Organization that described a global annual incidence of congenital toxoplasmosis of 190,100 cases (Torgerson and Mastroiacovo, 2013).

Tachyzoites may also be responsible for toxoplasmosis if blood or bone marrow, deriving from infected donors, are injected during transfusion or transplant, but it is rare (Gangneux and Dardé, 2012).

Toxoplasmosis in animals and humans

Infection in domestic animals

Toxoplasma gondii is capable of causing infection and severe disease in animals other than humans. Natural infection in cats can occur and the severity of the symptoms is correlated with the age, the stage of the parasite and the route of inoculation (in the case of

experimental infections). Pneumonitis is the most common finding in cats and it can be rapidly fatal. Infected cats can also show high fever, which is unresponsive to penicillin and streptomycin. Even if toxoplasmosis is often included in the differential diagnosis of neurologic disease, cats rarely have obvious neurologic signs. Other organs affected by toxoplasmosis include the eyes (multifocal iridocyclochoroiditis) and pancreas (pancreatitis).

In livestock animals, toxoplasmosis causes marked losses in sheep and goats, and may cause embryonic death and resorption, fetal death and mummification, abortion, stillbirth, and neonatal death in these animals (Innes et al., 2009).

Outbreaks of toxoplasmosis in pigs have been reported from several countries, especially Japan (Dubey et al., 1986), China (Li et al., 2010), Korea (Kim et al., 2009). Mortality is more common in young pigs than in adult pigs. Pneumonia, myocarditis, encephalitis, and placental necrosis have been reported to occur in infected pigs. Sporadic and widespread outbreaks of toxoplasmosis occur in rabbits, mink, birds, and other domesticated and wild animals. Animals that survive infection harbor tissue cysts, and can therefore transmit *T. gondii* infection to human consumers (Dubey et al., 2011).

The role of *T. gondii* infection in cattle is still under investigation. In fact, it does not have a relevant impact from a clinical point apart from some described cases of abortion, but in any case in a lower percentage compared to those caused by *Neospora caninum*. Worldwide seroprevalence ranged from 1% to 92% while the number of tissue cysts is extremely lower compared to pigs or sheep. Compatibly a metanalyses study identified a pooled *T. gondii* prevalence of 2.6% in bovine meat and cattle compared to pigs (12.3%) and sheep (14.7%) (Belluco et al., 2016). From one side we can confirm the low prevalence in cattle can be used to support the theory of limited bovine role in *T. gondii* epidemiology. However, the role of beef in *T. gondii* human epidemiology cannot be ruled out considering that this meat is often eaten raw or undercooked in several countries with a consequent high probability of infection with *T. gondii* (Belluco et al., 2016).

Chickens do not usually present clinical signs. Confirmed severe toxoplasmosis was first reported in a flock of 40 hens from Norway (Erichsen and Harboe, 1953). In some rare cases it was recorded a neurologic symptomatology; Goodwin et al. (1994), reported a peripheral neuritis in three chickens in United States diagnosed with immunohistochemistry (IHC), but also the Marek's disease could not be run out. One case of systemic toxoplasmosis (apathy, dyspnea and diarrhea and death 18 h after the onset of illness) in a quail from Brazil was recorded recently (Casagrande et al., 2015) with the presence of tachyzoites highlighted in a lot of organs through IHC and histology.

Infection in wild animals

Clinical and subclinical toxoplasmosis has been reported in many host species. Wild animals can be a source of *T. gondii* infection in humans, cats, and other carnivores. An Italian study conducted on red foxes, roe deers, wild boars, alpine chamois, red deers in Piedmont region (Northern Italy) revealed a higher prevalence of infection in carnivores and omnivores than in herbivores (no positive ones in this study). This reflects the higher probability of a carnivore or omnivore to consume tissues infected with *T. gondii* than the probability of an herbivore to ingest *T. gondii* oocysts from the environment (Ferroglia et al., 2014). The idea that tissue cysts are important as oocysts in the transmission of *T. gondii* and that wild animals (especially wild boar and roe deer) could be an important source of foodborne toxoplasmosis in humans was the same expressed by Smith and colleagues in United States (Smith and Frenkel, 1995).

Sea mammals have also been found positive for *T. gondii*. The parasite is considered a significant cause of encephalitis in sea otters (Cole et al., 2000). In a study conducted in 2002 from Cole et al. (2000) in 67 sea otters found dead or killed because of their inability to survive due to advanced disease or trauma, 15 (22.4%) were positive by bioassay. Miller et al. (2002) has documented a high prevalence (42–62%) of infection of southern sea otters with *T. gondii* in areas along the Pacific coast of United States resulting from surface water run-off contaminated with *T. gondii* oocysts. Several cases of *T. gondii* infection were confirmed in striped dolphins affected by Morbillivirus from the 1990–92 morbilliviral epidemic (Domingo et al., 1992), with lethal cases of *T. gondii* meningo-encephalitis being subsequently reported in striped dolphins stranded along the Ligurian Sea coast of Italy between 2007 and 2008 (Di Guardo et al., 2010).

Toxoplasmosis in humans

It is generally assumed that approximately 25–30% of the world's population is infected by *T. gondii* (Elbez-Rubinstein et al., 2009). The prevalence varies between countries and low seroprevalences (10–30%) are recorded in North-America, South East Asia, Northern Europe, Sahelian countries of Africa. Moderate prevalence (30–50%) have been found in countries of Central and Southern Europe, and higher prevalence in Latin America and in tropical African countries (Gangneux and Dardé, 2012).

Climate factors such as temperature and humidity influence the resistance of oocysts and as a consequence the level of infection. High prevalence are classically recorded in tropical countries (warm and humid) and lower ones in arid or colder countries. Other factors such as economic, social and cultural habits can explain the wide variations in human seroprevalence (dietary habits, methods of cooking meat, hand washing, water quality, risk knowledge associated with food consumption).

In a recent assessment of foodborne illnesses in the United States, toxoplasmosis was identified as the second leading cause of foodborne illness-related deaths and fourth leading cause of foodborne illness-related hospitalizations (an estimated 327 deaths, and 4428 hospitalizations annually) (Scallan et al., 2011; www.cdc.gov/parasites/toxoplasmosis). In Europe the WHO reported that 20% of foodborne-diseases is caused by *T. gondii* with about 1 million people infected every year (<http://www.eurosurveillance.org/12; www.who.int/en>).

Toxoplasma gondii and human health: Pathogenesis

Primary acquired infection in immunocompetent subjects is asymptomatic in more than 80% of cases in Europe and North-America. In the remaining cases patients show fever, cervical lymphadenopathy sometimes associated with myalgia or other non-specific clinical signs, very similar to a common flu (Montoya and Liesenfeld, 2004). Nevertheless, toxoplasmosis is life threatening if it occurs in immunocompromised patients. Patients with HIV/AIDS, transplants, those with cancer or with other diseases affecting the immune system, or treated with the so-called biological drugs are at risk for severe toxoplasmosis. A reactivation of a chronic infection may occur and this risk is related to the duration and degree of immunosuppression. HIV patients often develop encephalitis that leads to lethargy, ataxia, loss of memory, dementia, but the heart (myocarditis), lungs, eyes and pancreas may also be involved and parasite can be isolated from these tissues. Pulmonary or disseminated toxoplasmosis is seen mostly in transplant patients (Pereira-Chioccia et al., 2009; Gangneux and Dardé, 2012; Wang et al., 2017).

Congenital toxoplasmosis may occur in pregnant women and the severity of the consequences depends on the stage of pregnancy when maternal infection occurs. When a primary infection is acquired by a pregnant woman, tachyzoites can colonize placental tissue during the dissemination process and from there gain the access to the fetal compartment. Acute toxoplasmosis in developing foetuses may result in blindness, deformation, mental retardation or even death (Montoya and Liesenfeld, 2004). The frequency of vertical transmission increases with the gestational age at maternal infection. If the infection occurs in the first trimester of pregnancy the risk of abortion or severe abnormalities in the brain and eyes is high. During the second trimester, fetal infection can be of variable severity. Ultrasound echography (US) reveals areas of hepatosplenomegaly, cerebral calcification or areas of hyper-echogenic mesentery. At birth the baby may show epilepsy, anemia, thrombocytopenia-induced petechiae, rash, hepatic disorders, pneumonitis, or retinochoroiditis (Remington et al., 2001). This last clinical manifestation is a common feature that can be observed whatever the time of maternal infection. Although the vast majority of congenital infections result from primary acquired infection during pregnancy, parasite transmission can occur in rare instances in immunocompetent, previously immunized women who are re-infected with *T. gondii* during gestation. One such clinical case has been described due to an atypical strain of *T. gondii* (Elbez-Rubinstein et al., 2009).

Data from all over Europe, United States and South America (mainly from Brazil), identify *T. gondii* as a risk for human health. It is known that the majority of the population at risk of complications derived from toxoplasmosis, are mainly people with concurrent health issues (organ transplant, patients with cancer, HIV, etc.) and pregnant women who are at risk of abortion or severe congenital defects (Cenci-Goga et al., 2011; Gangneux and Dardé, 2012; Campos et al., 2014). However, a high incidence and severity of ocular toxoplasmosis in immunocompetent subjects and in congenitally infected babies, caused mainly by atypical strains, have been reported from Africa, Brazil and Colombia (Gilbert et al., 2008a,b; Huang et al., 2012, 2018). The prevalence of ocular toxoplasmosis varies from less than 1% to approximately 18% of persons, depending on geographical location. For the majority, ocular toxoplasmosis involves the posterior eye and is characterized by recurrent necrotizing retinitis, with frequent extension of the inflammation and tissue destruction into the choroid, which encapsulates the retina (Furtado et al., 2013).

Moreover, chronic toxoplasmosis has been shown to cause behavioral changes in mice, making them attracted rather than repelled by the scent of cat urine, due to inhibition of neuronal function and alteration of neurotransmitter levels (Gatkowska et al., 2012; Haroon et al., 2012). In humans, the condition has also been shown to correlate with schizophrenia and bipolar disorders (Sutterland et al., 2015).

Foodborne toxoplasmosis: The main food products at risk

As said before, the consumption of contaminated food is the major route of infection with *T. gondii* for humans. The potential risk associated with the consumption of products derived from infected animals including raw or undercooked meat products and in a very low percentage, milk, cheese made with unpasteurized milk, has been shown in numerous studies. Meat consumption is certainly one of the main transmission routes for the infection with *T. gondii*. Currently, there are no identification systems for the parasite at slaughter, in any animal species, neither in United States nor in Europe. Even if the recorded data about infection in retail meat are limited, one study showed a prevalence of only 0.33% in over 2000 samples analyzed (Dubey et al., 2005). This may lead to think that the risk for the consumers related to meat consumption is very low. On the contrary, the consumption of sausages, typical meat products such as raw ham, or undercooked meat which has not been frozen before eating, is strongly associated with food-borne infection in humans (Vitale et al., 2014; Bonametti et al., 1996; Choi et al., 1997). A quantitative microbial risk assessments (QMRA) based on data available in literature on *T. gondii* viability and ability to survive in certain conditions (i.e., salt concentration, temperature, humidity, etc.), on data about type and quantity of meat consumed in a certain country, economic conditions, etc. allowed the identification of beef as the most important type of meat responsible of *T. gondii* transmission, followed by pork and sheep meat (Opsteegh et al., 2011). Pork, poultry, beef and sheep (in lower percentage) are the main meats consumed in Italy, Europe and the United States (www.assocarni.it; Daniel et al., 2011).

All these species have been identified as intermediate hosts of *T. gondii* and parasite DNA or antibodies against a specific antigen have been recorded all over the world. The presence of DNA or antibodies against *T. gondii* indicate a previous contact with the parasite and, in the former case, certainly the presence of tissue cysts.

The importance of *T. gondii* as a risk for human health was recently highlighted by European Food Safety Authority's (EFSA) opinion on modernization of meat inspection, where the parasite was identified as a relevant hazard to be addressed in revised meat inspection systems for pigs, sheep, goats, farmed wild boar and farmed deer (Opsteegh et al., 2016).

Toxoplasma gondii was reported by the European Member States (MSs) from pigs, sheep, goats, cattle, wild animals and pets (cats and dogs) in 2017 and 2018. The highest overall prevalence of *Toxoplasma* infections in animals was detected in small ruminants (sheep and goats; 18.3%; 12 MS reported data) and in cattle (27.8%; 6 MS reported). Due to different diagnostic methods used (indirect methods detecting antibodies vs direct methods), different sampling schemes in the MS and the lack of information on the animals' age and rearing conditions it is not possible to make a real risk evaluation and to estimate the real prevalence of *T. gondii* in animals in EU (EFSA and ECDC (European Food Safety Authority and European Centre for Disease Prevention and Control), 2019).

The growing consumer demand for biological, free-range products in order to guarantee animal welfare and to have healthy food derived from them is another point to consider. Europe, together with North-America, is the main economic market for biological products, with an annual growth rate of 10–15% (Willer and Kilcher, 2009). Organic program standards (Anonymous (n.d.-a): Italian regulation DM n. 18354/09; Anonymous (n.d.-b): European Regulation CE 834/2007; Anonymous (n.d.-c): American legislation, USDA) require that all organically-raised animals must have access to the outdoors, including access to pasture for ruminants. Access to grass, soil, feed, or water contaminated with cat feces, or to rodents and wildlife infected with *T. gondii*, during outdoor pasturage substantially increases the risk of exposure of pigs, sheep, cows and chickens to the parasite. Kijlstra et al. (2004) found that none of the 621 conventionally raised pigs studied were seropositive for *T. gondii*, while 38 out of 1295 (2.9%) pigs raised in "animal friendly" management systems were seropositive for *T. gondii*, with a farm positive rate of 39.0%.

All that have access to the outdoors, including livestock and wild animals, have a potentially higher risk of coming into contact with the coccidian. This has already been demonstrated in several studies in the United States (Dubey et al., 2011, 2012) and Europe (Bacci et al., 2015; Vismarra et al., 2017a) in pigs, sheep, chickens, wildlife and also in derived products as milk.

Correct behaviours would lead to reducing the risk naturally associated with products derived from animals raised outdoors and at the same time all this would allow the development of a greater number of organic-organic farms in compliance with the dictates of animal welfare imposed by the European Commission.

Free-range chickens are a good indicator of soil contamination with oocysts because they feed from the ground and they rarely become ill from *T. gondii* (Ruiz and Frenkel, 1980; Dubey et al., 2011). Infected chickens are also an important source of infection for cats that in turn shed oocysts after eating tissues of this intermediate host. The ingestion of undercooked poultry may be a source of infection for humans. Freezing and cooking by conventional methods will inactivate tissue stages in meat. While meat is considered to be a major source of human exposure to *T. gondii* (WHO/FAO, 2016), little risk is attributed to chicken because it is typically well cooked (Kijlstra and Jongert, 2008). Pork, on the other hand, is considered a major source of human exposure (Dubey and Jones, 2008). Results of a recent study indicate that, while the density of *T. gondii* in poultry muscle is low, the ingestion of undercooked poultry muscle remains a potential source of infection for humans. The results showed that hearts of serologically positive chickens were used to infect cats and they all shed oocysts. Isolation of viable *T. gondii* from these free-range chickens is definitive evidence of the public health importance of the parasite (Dubey et al., 2015).

This risk can be significantly reduced if meat, milk and other products of animal origin are cooked (or pasteurized) adequately (minimum 67 °C for meat) and avoiding raw-cooked cross-contamination during the preparation of food in the kitchen. Commercial procedures of curing with salt, sucrose, or low-temperature smoking may kill tissue cysts, but the effect is strictly dependent on the combination of concentration of the solution with the temperature of storage. Authors reported for example that solutions containing 2% sodium chloride or 1.4% potassium or sodium lactate are effective within 8 h of injection in pork loin for the killing of *T. gondii* tissue cysts (Hill et al., 2006). On the other side, it was proved for example that Parma ham (from Italy) processing is able to kill the parasite in 12 months seasoning (Genchi et al., 2017), while Serrano ham (from Spain) was found positive for *T. gondii* in 9 and 12 months curing hams (Herrero et al., 2017). Recently, it was proposed that a High Pressure Processing treatment for at least 20 min at 600 MPa has to be applied on Spanish hams for a complete neutralisation (Gracia et al., 2020). Similarly, irradiation was also found to be effective against tissue cysts in meat (Lindsay et al., 2006). Finally, particular attention must be paid to vegetables, berries and fruits that can be contaminated by sporulated oocysts. In this case, an adequate washing under abundant running water is recommended.

Diagnosis in animals and humans

Diagnosis in animals

Diagnosis of toxoplasmosis is essentially based on the identification of a specific immune response against *T. gondii* through serology. We can choose among different types of serological tests to use as Enzyme-Linked Immunosorbent Assay (ELISA), agglutination (MAT), immunofluorescence (i.e., IFAT), Western Blot commercially available for humans, domestic animals and livestock animals. They allow the identification of IgM, IgG and also IgA. We can use serum or also meat juice (on muscle tissues of animal carcasses at slaughterhouse), depending on manufacturers' instructions and also oral fluids as recently reported in pigs (Campero et al., 2020).

IgM are commonly produced 2–4 weeks after infection and tended to disappear within 12–16 weeks in cats. On the other side IgG are expression of a non-recent infection. They could be found in the blood already 3 weeks after the contact and since *T. gondii*

infection tends to remain latent rather than resolve, IgG remain throughout the life of the animal. It is also important to remember that a high IgG titer is neither symptom of an acute infection, nor of a reactivation of the parasite. They have been described cases of healthy cats with recorded IFAT values higher than 1:10,000 many years after the first contact with *T. gondii*. Similarly, also in case of re-activation of infection by the encysted parasite no increase in the antibody titer was reported, both in animals and humans (Lappin et al., 1989). At the same time, low IgG values should be due to phenomena of analytical variability. It is also important to remember that during the shedding cats are usually negative to serological tests because the synthesis of antibodies required at least 2–3 weeks and at that point cats have already finished to shed oocysts. This lead that a seropositive cat will no longer eliminate oocysts with feces, except in rare cases of re-shedding.

A visual fecal exam should be made on cat feces through flotation for the *identification of oocysts* (Dubey et al., 2011). It is a *standard fecal flotation* using sucrose solution 1.15 gravity made with 53 g of sugar, 100 mL of water, 0.8 mL of liquid phenol or 2% sulfuric acid. However, this type of diagnosis requires qualified personnel and also in this case the chance to find oocysts is low. In fact, two studies made in United States reported that less than 1% of the analyzed cats (about 600) shed oocysts (Dabritz et al., 2007; Spain et al., 2011). This could be explained because after the first contact with the parasite, cats, especially young cats, shed oocysts for only 1–2 weeks and in this period they usually did not show any clinical sign.

The *identification of tachyzoites* is not so easy to do because they are present in blood or other body fluids only during active stage of infection, so for only short periods of time. On the other side, their identification allows a clear and certain diagnosis of toxoplasmosis. Materials such as cerebrospinal fluid, aqueous humor, or obtained from needle-aspiration from numerous tissues (e.g., lymph nodes) and body fluids (broncho-alveolar or trans-tracheal lavage or fluids from peritoneal or thoracic effusion) can allow the detection of tachyzoites through cytological examination. Similarly, histology and immunohistochemistry should be applied on biopsies from different body districts.

Polymerase chain reaction can be used for *T. gondii* identification and it is applicable on biopsies, on aqueous humor samples, on cerebrospinal fluid (CSF), on broncho-alveolar lavage (BAL), in blood (even if it is rare to find tachyzoites as described before), on muscle tissues of slaughtered animals for food safety purposes for example and in cat's feces positive for oocysts. In this case PCR allows a differential diagnosis with respect to *Hammondia* or *Besnoitia*. In the other cases, PCR is able to identify and differentiate the parasite but it is important to remember that the presence of DNA does not necessarily correlate with a viable and infectious parasite (also for this reason the gold standard to prove the presence and viability of the parasite is, still today, the bioassay). The genetic markers most commonly used are the B1 gene, the 529 bp repeat marker, but there are also others as SAG1, SAG6, APICO, etc. A PCR targeting the 529 bp repeat element has been reported to be 10–100 times more sensitive than the B1 gene (Homan et al., 2000), even if B1 is more specific. There are several PCR methods available and applicable for identification of *T. gondii* as nested PCR, used to increase the specificity of DNA amplification as well as to detect very few amounts of parasite. Real-time PCR (Rt-PCR) based methods allowed both the identification and quantification of the parasite and have a high degree of complex-specific diagnostic accuracy for diagnosis of pathogens in clinical samples. These assays are more rapid, sensitive and reproducible than conventional PCR, in fact when the target DNA is in low concentration, Rt-PCR is the most sensitive molecular assay for the detection of pathogens. Different protocols have been proposed and the majority of the studies reported that it is more sensitive compared to other molecular and biological methods (Calderaro et al., 2006; Juránková et al., 2013).

Loop-mediated isothermal amplification (LAMP) is a one-step PCR characterized by high sensitivity, specificity, efficiency. Moreover, it is also easy to perform, feasible, rapid and does not require expensive instruments (as Rt-PCR needs for example). LAMP amplifies DNA under isothermal conditions (60–65 °C) using a DNA polymerase (*Bst*) with strand settlement activity and 4–6 specific primers, which are able to recognize a total of 6–8 distinct regions within the target DNA, increasing significantly the specificity of the method (Abbasi et al., 2010). LAMP is used for *T. gondii* detection in several biological and environmental samples amplifying different targets as B1, 18S rRNA, SAG1 (Lalle et al., 2018; Wang et al., 2013).

Bioassay is still now the “gold standard” to demonstrate the presence of live and infectious *T. gondii* in animals and food products. Their use has been strongly limited in recent years after the development of a specific legislation on animal welfare, the so-called “3R” rules (replacement-reduction-refinement). Mice are commonly used and infected with intraperitoneal injection for increasing the number of tachyzoites, useful for lab experiments (i.e., drugs test in vitro) for example, or to check the presence of *T. gondii* in meat or food samples (i.e., after a treatment with UV, high pressure, different time-temperature conditions, etc.). Also cats might be used, in this case they are infected orally and the presence of the parasite is demonstrated if infected cats shed oocysts.

Currently, bioassay using either cats or mice is the standard method to demonstrate *T. gondii* viability but, for ethical reasons, this is not preferred for large scale testing as has, for example, become evident from the recent closure of these facilities at the United States Department of Agriculture (USA) (USDA Press Release No. 0042.19) (Opsteegh et al., 2020).

Alternative methods as *cell culture* combined with a Rt-PCR (Vismarra et al., 2017a; Zintl et al., 2009) have been proposed and the method seems promising. Anyway, critical points are still present as tissue digestion, since the presence of digest affected sensitivity, and issues with PCR inhibition and fungal contamination were encountered (Opsteegh et al., 2020).

As already cited meat is probably the principal food product responsible for *T. gondii* transmission to humans (Scallan et al., 2011). The problem is that the sole gold standard for identification of *T. gondii* in meat is the bioassay in cats or mice, with obvious bioethical implications. Serological tests are useful to prove if contact with the parasite has occurred, but cannot certify the presence of tissue cysts. Moreover, various PCR methods have been developed, but the sensitivity was low because of small amount of DNA, low amount of meat that can be tested, together with a low tissue cyst density. For all these reasons researchers tried to develop an alternative method enough sensitive and specific to use instead of bioassay: *the magnetic capture Rt-PCR*. The method combined the hybridization of specific, biotinylated probes with the capture of those probes with streptavidin-coated paramagnetic beads together

with a Rt-PCR reaction. In this way *T. gondii* DNA can selectively be “fished out” from a large volume of meat lysate. The last version of the method was validated as ISO 17025 with a 99% detection limit of 65.4 tachyzoites per 100 g of meat, so more sensitive and economic (Algaba et al., 2017).

Diagnosis in humans

Diagnosis in humans is mainly based on *serology*. Depending on countries and relative monitoring control programs, generally pregnant women are subjected to serological test for *T. gondii* at the beginning of pregnancy and if they are seronegative, every month till the birth (at least in developed countries). Tests include the research of IgM and IgG antibodies with ELISA test, Sabin-Feldman dye test or other lab methodologies. The newest techniques for the research of anti *T. gondii* immunoglobulins are chemiluminescence assays (CLIA), enzyme-linked fluorescence assay (ELFA), immunochromatographic test (ICT), serum IgG avidity test and immunosorbent agglutination assays (ISAGA) (Rostami et al., 2018). In ISAGA, anti-human IgM antibodies are used for diagnosis of acute or congenital toxoplasmosis. A disadvantage for this method is the requirement of a large numbers of *T. gondii* tachyzoites. Although, this problem was resolved by replacing *T. gondii* tachyzoites with latex beads coated with soluble antigens (Liu et al., 2015). The last developed serological tests exploited the recombinant antigen technology, in this way sensitivity, specificity, repeatability of the tests are guaranteed without the need of a huge amount of tachyzoites and the need for standardization at each laboratory. Moreover, different antigens, specific of acute and chronic phase of infection, could be tested simultaneously, discriminating between the two stages of *T. gondii* (typically SAG1 for tachyzoites and BAG1 for bradyzoites) (Holec-Gąsior, 2013). In addition, more recent studies using chimeric antigens and multiepitope peptides reported very promising results. In fact, these chimeric and/or synthetic peptide antigens, including different immunoreactive epitopes from various strains of *T. gondii*, that are also hydrophobic and generally well exposed on the antigen surface, seem to be strongly able of discriminating recently acquired infections from chronic one (Dai et al., 2012). New recombinant proteins, as TgERP (Hill et al., 2011), have been designed with the aim to develop diagnostic systems able to discriminate between a *T. gondii* infection due to ingestion of oocysts or tissue cysts. In 2015, for example, researchers created the CCp5A recombinant protein from oocyst/sporozoite of *T. gondii*. It was reported to be a potential new tool for diagnosis and epidemiological studies since the CCp5A protein reacted only with serum of pigs, chickens and mice infected with oocysts and it is able to detect both IgM and IgG in serum of people from an outbreak of toxoplasmosis and also in serum of pregnant woman (Santana et al., 2015).

IgG, IgA and IgM specific for *T. gondii* could also be found in saliva and oral fluid at different concentrations depending on several factors with results comparable to serum (Hajeer et al., 1994; Mangiavacchi et al., 2016). IgG in particular are considered good markers for acute toxoplasmosis (Hajeer et al., 1994; Sampaio et al., 2020) and used for diagnosis and monitoring of infants with suspected congenital toxoplasmosis (Chapey et al., 2015a). Moreover, also the interferon gamma release after T-cell stimulation by *T. gondii* antigens has been proven to be useful for the diagnosis of congenital toxoplasmosis (Chapey et al., 2015b). Interferon-gamma release assay (IGRA) accurately distinguished infected from uninfected individuals, showing strong lymphocyte activation after *in vitro* stimulation with *T. gondii* antigens, even during the first days of life. New tools following this principle have been developed as for example the ELISA-based IGRA test, reported as an easy-operation and low-cost method to measure cell mediated immunity against *T. gondii* (Mahmoudi et al., 2017).

To overcome the limitations of the serological tests, different *molecular methods* have been developed to detect *T. gondii* DNA in biological samples.

To diagnose congenital and ocular toxoplasmosis, the PCR has been successfully used with amniotic fluid, placental and brain tissues, aqueous humor and vitreous fluid. Moreover, whole blood, urine, CSF, BAL, pleural and peritoneal fluids have been effectively used to diagnose toxoplasmosis in immunocompromised patients. The most used target also in clinical setting are the B1 gene as well as the 529 bp repeat element.

Imaging techniques are useful for diagnosis of cerebral and ocular toxoplasmosis.

A variety of techniques as computed tomography (CT), magnetic resonance imaging (MRI), nuclear imaging and US could be applied to diagnose cerebral toxoplasmosis (encephalitis) (Rostami et al., 2018).

The ocular toxoplasmosis can be diagnosed by clinical findings such as visual acuity, intraocular pressure, biomicroscopy and indirect ophthalmoscopy but also with the help of imaging techniques such as fundus autofluorescence (FAF), confocal scanning laser ophthalmoscopy (CSLO), optical coherent tomography (OCT), fluorescent angiography (FA), ultrasound, and indocyanine green angiography (ICG) (Rostami et al., 2018).

Congenital toxoplasmosis on the other side might be diagnosed with US to identify brain abnormalities. Similarly, US can be used postnatally also to monitor ventricular size in infants till 18 months of age (Khan and Smirniotopoulos, 2015).

In adult peoples hepatosplenomegaly and abdominal lymphadenopathy due to toxoplasmosis might be identified with an abdominal US.

To conclude, for a correct diagnosis of congenital toxoplasmosis several medical protocols suggest to apply IgG/IgM ELISA in combination with Rt-PCR/LAMP on amniotic fluid and prenatal US for detection of acute infection in pregnant women. Serology is also the “gold standard” in newborns, although Rt-PCR/LAMP on cord blood or whole blood can be useful for definitive diagnosis.

Moreover, combining of ELISA (using TLA, recombinant or chimeric antigens), Rt-PCR/LAMP on CSF and imaging findings by MRI or CT could result in definitive diagnosis in immunocompromised patients.

Drug treatment

Regarding drug therapy, the treatment of cats with clinical toxoplasmosis is mainly based on the use of clindamycin, with dosages of 20–25 mg / kg for 1–2 weeks in the case of intestinal forms and of 20–40 mg / kg for 2–4 weeks in the case of systemic forms. Clinical signs generally improve 24–48 hours after the start of treatment, however the side effects can be important and manifest themselves with gastroenteritis and diarrhea (Davidson, 2000). Generally, most of the clinical signs related to toxoplasmosis tend to strongly decrease after 7 days of treatment, if this does not happen, prolonged use of the same molecule will hardly produce the desired effects and for this reason it is advisable to change the drug (Lappin, 2010).

In the case of systemic pathology and uveitis, it is recommended to administer clindamycin with glucocorticoids topically, parenteral or oral, to avoid glaucoma or dislocation of the lens as a secondary outcome of the infection. In case of systemic manifestations, the use of pyrimethamine and sulfonamides in combination has also been described. Also in this case, side effects can be important, in particular for the myelosuppressive action of these drugs. In the case of neurological forms, the administration of anti-convulsants may be necessary (Dubey et al., 2009). In addition, treatment with clindamycin, sulfonamides and pyrimethamine can reduce the elimination of oocysts with faeces in cats infected for the first time with *T. gondii* (Dubey and Lappin, 2006).

It is important to remember that the drugs against *T. gondii* do not eliminate the parasite but only stop its replication. As a defense mechanism against the host's immune response, coccidium "hides" in the musculoskeletal and cerebral tissues and the formation of cysts containing bradyzoites protects the parasite from attack by pharmacological molecules and blocks the action of monocytes, macrophages and other immune cells (Dunay et al., 2018). In fact, the main problem in finding effective treatments for toxoplasmosis is the inability of lots of molecules to reach tissue cysts and acting against bradyzoites. Actually, the two drugs mainly used for treating human toxoplasmosis (active against the "free form" of the parasite) are Pyrimethamine and Sulfadiazine. The first one, typically used for malaria, is a folinic acid antagonist and other potential side effects include bone marrow suppression and liver toxicity, while Sulfadiazine is an antibiotic (Class: sulfonamides).

Actually, in case of seroconversion which occurred after the 18th week, the guidelines generally foresaw a treatment with Spiramycin or a protocol with Pyrimethamine, Sulfadiazine and Folinic Acid with the aim of avoiding the manifestation of congenital toxoplasmosis. On the other hand, in case of congenital toxoplasmosis the therapeutic protocol foresaw the administration of Pyrimethamine + Sulfadiazine + Folinic Acid (Pyrimethamine 1 mg / kg / day for 2 months, then 0.5 mg / kg / day; Sulfadiazine 50 mg / kg 2 times a day; Folinic Acid 1 tablet of 25 mg 2 times a week) or Sulfadiazine + Pyrimethamine + Folinic Acid (Sulfadiazine 17.5 mg / kg once a week; Pyrimethamine 0.875 mg / kg once a week; Folinic Acid 1 tablet of 25 mg twice a week) (Peyron et al., 2019).

About vaccination, to date, there is no anti-*T. gondii* vaccine effective in blocking the vertical transmission of the parasite or in eliminating brain and tissue cysts, despite the fact that numerous antigenic determinants capable of inducing a humoral immune reaction have been identified. Currently, the only anti-*T. gondii* vaccine is intended for sheep and is only authorized in some countries such as New Zealand, France and Great Britain, excluding Italy. This is due to the fact that it is a live attenuated vaccine containing tachyzoites and therefore potentially risky. Furthermore, not everyone agrees on its real effectiveness.

History

The parasite was fortuitously discovered in 1835 by Richard Owen and James Paget in the muscles of a dead patient. It was diagnosed as a “microscopic entozoon infecting the muscles of the human body.” The pathogenic role of the parasite for humans was revealed by Friedrich Albert von Zenker in 1860 after the finding of the parasite in the muscles of a young woman (who died of trichinellosis) and also in the eaten meat. The parasite was first called *Trichina spiralis*, then *Trichinella spiralis* in 1896.

Epidemiology

Trichinella spp. are widespread in wildlife on all continents (except probably Antarctica) and in domestic pigs of many countries (Murrell and Pozio, 2011). The natural cycle is maintained by a large number of infected vertebrates (≈ 100 animals species), divided into three classes: mammals, birds, and reptiles. Man, an accidental host, is a parasitic dead end. Ten species and three genotypes are recognized by molecular analyses in the genus *Trichinella* (Korhonen et al., 2016), namely, *Trichinella spiralis* (T1), *Trichinella nativa* (T2), and its related genotype *Trichinella* T6, *Trichinella britovi* (T3), and its related genotype *Trichinella* T8, *Trichinella pseudospiralis* (T4), *Trichinella murrelli* (T5), and its related genotype *Trichinella* T9, *Trichinella nelsoni* (T7), *Trichinella papuae* (T10), *Trichinella zimbabwensis* (T11), *Trichinella patagoniensis* (T12), and the last described *Trichinella chanchalensis* (T13) (Pozio and Zarlenga, 2013; Sharma et al., 2020). All species can develop in mammals, but *T. pseudospiralis* can also develop in birds, and *T. papuae* and *T. zimbabwensis* also occur in some reptile species (Pozio, 2007) (Fig. 1).

There is a wild cycle and a domestic cycle, both are more or less intertwined. The wild cycle is maintained by a large number of invertebrates that become contaminated by the ingestion of live prey or infested carrion. *T. spiralis* and *T. pseudospiralis* are globally distributed (La Rosa et al., 2003; Rosenthal et al., 2008), whereas the other species are geographically restricted. In temperate regions, *T. spiralis* and *T. britovi* infect wild boars, canids, viverrids, mustelids, and marsupials. In the tropics, *T. nelsoni* infects large carnivores, scavengers, and warthogs. *T. papuae* infects pigs in New Guinea and Southeast Asia (Caron et al., 2020). In the polar regions, *T. nativa* and *Trichinella* T6 infect bears, canids, and walruses. The domestic cycle is maintained by pigs, rodents, and accidentally horses. Pigs are responsible for the majority of epidemics around the world. It becomes infected by ingesting rodents or by tail-biting. Herbivores, such as horses, sheep, or goats, would become contaminated because of the accidental presence of animal waste in their food (Soule et al., 1989; Rostami et al., 2017).

The most common source of human trichinellosis is meat from pig or wild pig (*Sus scrofa*) (Gottstein et al., 2009; Murrell and Pozio, 2011). The disease is endemic in regions where pig farming is traditional, veterinary controls are absent or insufficient and this meat is consumed raw or undercooked. Moreover, large outbreaks linked to the consumption of horse meat are reported; and small outbreaks occur due to the consumption of game meat (wild boar, bear, warthog, reptile, etc.). Travel in regions with high incidences is a classical driver for acquiring trichinellosis (Dupouy-Camet, 2014; Barluet et al., 2020).

Approximately 11 million persons worldwide might be infected by *Trichinella* spp. (Dupouy-Camet, 2000). A total of 65,818 human cases of trichinellosis and 42 deaths have been reported in 41 countries from 1986 to 2009 (Murrell and Pozio, 2011): In Africa, Asia and America, parasitosis is rarely reported (0.04, 2.37, and 10.90% of cases, respectively). In Africa, outbreaks have been described in natives from Christian regions of Ethiopia or in European travelers to Algeria and Senegal. In America, most of the cases are reported in Argentina. In Canada and Greenland, a few outbreaks occurred in native people and foreign hunters. In Asia, most of the cases are reported in China; but the parasitosis could be underestimated in some regions, for example in Vietnam (Caron et al., 2020). Europe matters the higher number of cases (86.47%). Eastern European countries reported particularly most cases (Romania, Serbia, Bulgaria, and Lithuania). Since the early 1990s, the incidence of the disease has decreased in this region.

Parasitology

Cycle

The adults are a few millimeters long. The microscopic larvae, sources of contamination, are most often present in the striated skeletal muscle fibers of the infected animals. After eating parasitized meat, larvae are released by stomach digestion and become adults within 48 h in the small intestine. The adults die in less than 4 weeks; after mating, the females lay, 5 to 15 days after the contamination, thousands of larvae. The newborn larvae (NBL) migrate, through the lymphatic-blood route, into the general circulation before moving to the muscle fibers. There, the NBL diverted the metabolism of the host cell, which will become a nurse cell (NC), they will encyst 3 weeks after contamination and will survive for several years. Although the parasite is transmitted by carnivorous, herbivores can be sources of contamination (Rostami et al., 2017). Currently, the 13 lineages of *Trichinella* are grouped into encapsulated and non encapsulated clades based on the presence or absence of a collagen layer surrounding the NC containing the infective larva stage 1 (L1) (Zarlenga et al., 2006; Pozio and Zarlenga, 2013). Interestingly, the three non encapsulated species are those that can develop in other animals than mammals, *T. pseudospiralis* (T4) in birds, *T. papuae* (T10) and *T. zimbabwensis* (T11) in some reptile species (Pozio, 2007). Seven *Trichinella* species have been found pathogenic for humans, *T. spiralis*, *T. nativa*, *T. britovi*, *T. murrelli*, *T. nelsoni*, and *T. pseudospiralis* and *T. papuae* (Fig. 2).

Pathogenicity

Parasite factors

Adult females play a role in the pathogenesis by mechanical and irritant action on the intestinal mucosa leading to its penetration, or by toxic and antigenic action in releasing of excreted secreted (ES) products, and by limited bactericidal action. The larvae have also a pathogenic role through their toxic and irritant action during encystment in muscle, and an antigenic action leading to the activation of the host's immune system.

Fig. 1 The evolution and biogeography of *Trichinella* taxa. (A) The phylogeny of all 12 currently recognized taxa of *Trichinella* based on analyses of amino-acid sequence data from shared single-copy orthologous genes SCOs ($n = 1284$) employing Bayesian inference, ML and MP methods, with *Trichuris suis* and *A. suum* as outgroups; 1042 and 747 are the numbers of orthologous gene groups, which are unique to encapsulated (red) and non-encapsulated (blue) *Trichinella* taxa, respectively. The topology of the trees constructed using each of these methods was the same; all nodes have absolute statistical support (1.00 or 100%), except for one node (*) in the ML analysis, where it was 99%. The grey bars on the nodes represent 95% confidence intervals for the estimate of species branching time. *T. spiralis* (ISS195) shares the same phylogenetic position (**) as *T. spiralis* (ISS3). Host animals: suids (*Sus scrofa*) represent both the sylvatic and domestic porcine hosts (left); the reproductive potential of a particular *Trichinella* taxon in *S. scrofa* is indicated by the color scale: white: not assessed; light grey: low; dark grey: medium; black: high. Other animals (right) represent examples of carnivorous sylvatic hosts in different geographic regions, including fox, lion, mountain lion, marsupial, crocodile and bird of prey, and the accidental human host. (B) Representation of genome-wide synteny among *Trichinella* taxa (same order as listed on the right in A). Genomic scaffolds (black) sharing at least 10 SCOs between *Trichinella* taxa are displayed. A purple line indicates a single SCO and a red line an inverted SCO. The numbers on the right indicate the genomic length in megabases (Mb). (C) Biogeography of *Trichinella* taxa proposed on the basis of known global (climate, extinctions and/or tectonic) events and diversification times (mya) for *Trichinella* taxa, estimated using a molecular clock approach. Encapsulated taxa: *T. spiralis*, T1; *T. nativa*, T2; *T. britovi*, T3; *T. murrelli*, T5; *T. nelsoni*, T7; *T. patagoniensis*, T12; and *Trichinella* genotypes T6, T8 and T9. Non-encapsulated taxa (infecting mammals, reptiles and/or birds): *T. pseudospiralis*, T4; *T. papuae*, T10; *T. zimbabwensis*, T11. Geographic distributions of *Trichinella* taxa were reported by Pozio and Zarlenga. The embedded public domain world map image (<https://commons.wikimedia.org/wiki/File:BlankMap-World6.svg>) has been modified using the programs World map tool v.1.16 (<http://law.nagoya-u.ac.jp/en/appendix/software/worldmap>) and GIMP v.2.8 (<https://www.gimp.org/>), <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4740406/bin/ncomms10513-f1.jpg>. From Korhonen PK, Pozio E, La Rosa G, Chang BC, Koehler AV, Hoberg EP, Boag PR, Tan P, Jex AR, Hofmann A, Sternberg PW, Young ND, and Gasser RB (2016) Phylogenomic and biogeographic reconstruction of the *Trichinella* complex. *Nature Communications* 7: 10513.

The degree of pathogenicity of *Trichinella* is directly related to the species as the females have different fertility rates (Sadaow et al., 2013) and to the initial infecting dose (Pozio et al., 1992; Murrell et al., 2000; Gottstein et al., 2009). *Trichinella spiralis* is considered the most pathogenic species. One larva per gram of meat is enough to cause clinical signs in humans, corresponding to an infectious dose of around 150 larvae in a usual ration of meat (Zarlenga et al., 2006).

Fig. 2 Life cycle of *Trichinella* in humans and main sources of contamination. From Dupouy-Camet J, Lacour S, Vallée I, Yera H, Boireau P. (2015) Trichinelloses. *Encyclopédie Médico-Chirurgicale - Maladies infectieuses* 12(2): 1–13. DOI 10.1016/S2211-9698(15)57764-9.

Host susceptibility

The nature of the host influences the parasite infectivity. *T. spiralis*, *T. pseudospiralis* and *T. papuae* appear to be more infectious (i.e. greater reproductive capacity) in hamsters and gerbils than in mice and rats (Sadaow et al., 2013). Age influences the severity of the disease. Old people have more risk of complications (Barruet et al., 2020; Dupouy-Camet and Bruschi, 2007). The immune status also influences the severity of the disease. People, that had previous contact with *Trichinella* parasites, may develop an immunity, leading to a longer incubation phase and milder symptomatology in case of reinfections. Such immunity has been observed in Inuit populations having frequent contact with infected meat (Viallet et al., 1986) and during small outbreaks in France and Serbia (Dupouy-Camet et al., 2016; Barruet et al., 2020).

Type of meal

The quantity of alcohol consumed during the meal can affect the virulence of the parasite (Steven et al., 1990; Na et al., 1997). The type and duration of meat treatment, or the cooking mode of the meat, as well as the quantity of treated or prepared meat influence the survival of larvae. The survival of *Trichinella* in dried meat depends on the moisture content (Gamble et al., 2007).

Physiopathology

Infection is clinically manifest in humans when the number of larvae per gram of muscle biopsy is about 10 and can become severe when this number is greater than 100 (Pawlowski, 1983). Complications are linked to the toxic effect of eosinophils in large numbers in the tissues (Durack et al., 1979; Katz et al., 1989; Mawhorter and Kazura, 1993) and the migration of larvae in the tissues. So, heart and brain lesions are often associated and could result from the simultaneous intervention of local prothrombotic effects of eosinophil activation and vascular injury caused by the migrating larvae (Fourestie et al., 1993).

Immunity

Trichinella adults and larvae are responsible for an immune response at intestinal, systemic, and tissue levels, respectively.

During the intestinal phase

The infection causes infiltration of inflammatory cells (lymphocytes, mast cells, and eosinophils) in the lamina propria of the intestinal mucosa. The CD4 + T lymphocytes (TL) recognize the parasite antigens and are activated within 2–4 days post-infection. A Th1-type immune response sets in with the release of interferon γ and interleukins (IL) 2 and 3 in the mesenteric ganglia. Interferon γ allows the activation of macrophages. IL 2 stimulates the proliferation of T and B lymphocytes. IL 3 allows mast cells to release mediators (proteinases with chymotryptic activity, “platelet activating factor” PAF, “eosinophil chemotactic factor” ECF-A, leukotrienes, histamine and, serotonin) which modify intestinal motility allowing the expulsion of adult worms from the intestine. The goblet cells prevent contact between the parasite and the intestinal epithelium by hypersecretion of mucus (Bell, 1998; Bruschi and Chiumiento, 2012).

During the migratory phase

Eosinophils appear during NBL migration and allow their elimination, at least in a secondary infection (Bruschi, 2002; Bruschi and Chiumiento, 2011; Huang and Appleton, 2016).

During the muscle phase

The entry of the parasite produces chronic inflammation in the muscle of the host. A Th2-type immune response sets in with the release of IL 4, 5, 6, 10, and 13. This lasts throughout the chronic phase of the infection. Specific IgG and IgE antibodies are produced in high quantities, the levels of IgM and IgA are lower.

IL 4 and 10 stimulate the synthesis of IgE. IL 4 also participates in the transport of IgE in the intestine and stimulates the proliferation of mast cells in the intestinal mucosa. This cytokine plays a role in the expulsion of worms from the intestine. IL 5 and 6 promote the development of eosinophils.

In vitro eosinophils and neutrophils can kill NBL by antibody-dependent cell-mediated cytotoxicity (ADCC), whereas in vivo their role is not yet clear (Bruschi and Chiumiento, 2012). The cellular infiltrate around the NC is composed of macrophages, CD4 +, CD8 + TL, and some B lymphocytes (Finkelman et al., 1997; Bell, 1998; Bruschi, 2002; Bruschi and Chiumiento, 2011).

Variability according to parasite species

Pig model studies showed that host immune response differs according to the parasite species. Seroconversion occurred slowly with *T. pseudospiralis*, as with *T. britovi* compared to *T. spiralis*. The highest infectivity and immunogenicity, and the longest larvae survival in muscles were found with *T. spiralis* (Pozio et al., 2020).

Variability of host's response

The host's response to *Trichinella* infection is highly variable, believed to be related to the major histocompatibility complex (MHC).

Host's immune system escape strategies

Animal model studies showed that *T. spiralis* and its products induce an immunomodulatory network (which encompasses Th2- and Treg-type responses) (Sofronic-Milosavljevic et al., 2015).

Antigen dependent mechanisms

In muscle, *Trichinella* will seclude itself from the host's immune system through the formation of the NC and the collagen capsule. From this immunologically privileged place, the parasite orchestrates a long-lasting molecular cross-talk with the host. The maintenance of the NC is possible thanks to the exchanges between the parasite and its host. These exchanges depend essentially on secreted signal molecules such as muscle larvae ES products and cytokines. ES products originate from stichocyte granules in the stichosome, secretory organelle of the *T. spiralis* muscular larvae (Despommier, 1983; Cvetkovic et al., 2016). Host cells respond to molecular signals by participating in the formation of the NC (Despommier, 1998; Bruschi, 2002; Bruschi and Chiumiento, 2012). The *T. spiralis* cuticle is a dynamic organ that undergoes protein changes during the molting process and growth. The modification of the parasitic surface antigens allows *Trichinella* to escape the action of effector cells of the host's immunity (Phillipp et al., 1980).

Modulations of the host's immune system

Trichinella can modulate the production and functions of the host's immune cells.

At the central level

During the production of NBL, immunosuppression occurs, which suggests that NBL release lymphocytotoxic factors. The parasite also stimulates the production of eosinophils decreasing the Th1-type immune response, which is harmful to the parasite. The parasite stimulates the polyclonal activation of lymphocytes, which may contribute to the increase of non-specific IgE in favor of specific IgE.

At the peripheral level

Antigens secreted by the parasite may also interfere with the maturation of antigen-presenting dendritic cells, thereby promoting a Th2-type response (Ashour, 2013). They could also stimulate the production of regulatory TL which inhibit the production of other effectors TL (Aranzamendi et al., 2012).

L1 ES proteins inhibit the chemotaxis of neutrophils. ES products of *T. spiralis* could modulate the functions of macrophages, in particular by reducing their capacity to express pro-inflammatory cytokines (TNF α , IL 1, IL 6, and IL 12) in the presence of lipopolysaccharide (LPS) (Bai et al., 2012; Zawistowska-Deniziak et al., 2021). *Trichinella* is thought to induce specific antibodies capable of blocking the ADCC of eosinophils and neutrophils against NBL. The parasite may produce compounds able to inhibit the assembly and polymerization of the membrane attack complex (MAC), preventing damage to the complement system. *T. spiralis* and *T. nativa* can activate the complement system and escape its attack (Nareaho et al., 2000).

Clinics of trichinellosis

Clinical signs are related to the infected dose, the species of *Trichinella*, and the host (see Parasitology section).

Acute trichinellosis

Classically, trichinellosis manifests itself in three phases: an incubation phase; an acute phase or invasion phase, and a convalescence phase (Dupouy-Camet and Bruschi, 2007) (Table 1).

During incubation (1 to 4 weeks), diarrhea is most often observed (but in less than 50% of cases), as well as vomiting or abdominal pain. These first digestive symptoms correspond to the presence of adult worms in the intestine (2 days to 4 weeks after contamination). They last an average of 10 days. During the acute phase (1 to 4 weeks), the patient has a fever, swelling of the face and eyelids, severe muscle pain, asthenia. These general symptoms are present in more than three-quarters of the cases. They correspond to the NBL circulation (5–15 days after the contamination); then to their migration into the muscles. Fever could be high ($>39^{\circ}\text{C}$) and associated with pruritus and urticarial or morbilliform rash on the trunk, the abdomen, and limbs. Facial edema may be palpebral and/or conjunctival. It appears between 7 and 25 days after the contamination. Fever and edema last an average of 10 days. Conjunctivitis or subconjunctival bleeding are sometimes present. Peripheral edemas have been described. Distal subungual hemorrhages, specific to disseminated vasculitis, are sometimes observed. Myalgia and asthenia persist for 2–4 weeks. At this phase, there is an increase in eosinophils and muscle enzymes in the blood. During the convalescence phase, myalgia and asthenia persist longer.

Main complications

Complications could sometimes occur during the acute phase and mainly in the elderly. Neurological, cardiac, and vascular damages are responsible for the severity of trichinellosis. Their frequencies are variable according to epidemics and can affect up to 30% of cases for neurological complications and 4 up to 20% for cardiac and vascular complications, respectively (Ancelle et al., 1998; Dupouy-Camet and Bruschi, 2007). They can be life-threatening. The reported mortality rates of trichinellosis in humans are 0.2 to 0.5%, but a high rate of 24% was observed in an outbreak in Cambodia where the infective doses were certainly very high (Caron et al., 2020).

Neurotrichinellosis represents the major complication of trichinellosis in humans. It is caused by vasculitis, small vessel thrombosis, punctiform hemorrhages, ischemia, and granulomatous inflammatory reactions often involving eosinophils (Cortez et al., 1986; Soulié et al., 1986). Neurological involvement may present as meningoencephalitis or focal neurological signs or coma.

Table 1 Clinics and diagnosis of trichinellosis.

Phase	Duration	Symptomatology	Blood biology
Invasion phase	1–4 weeks	Unapparent or digestive disorders – Diarrhea – Abdominal pain	Eosinophilia
Acute phase	3–4 weeks	Fever, myalgia, edema (face), bleeding (rare) – subconjunctival – subungual, and complications	Eosinophilia, muscle enzymes increase, positive serology
Convalescence and chronic phases	Months, years	Myalgia, asthenia	Positive serology

Therefore, the symptoms are very polymorphic: disorientation, frontal syndrome, hemi- or quadriplegia, oculomotor deficit, central visual deficit, aphasia, cerebellar syndrome, facial nerve paralysis, seizures, etc. . .). Symptoms last from 1 to 2 months, but motor or neuropsychological sequelae may persist after 6 months.

Cardiac involvement manifests in myocarditis. Pericarditis, endocarditis, wall thrombosis, or coronary artery can rarely be observed. These complications must be systematically sought by EKG. The symptoms include pain in the heart region, tachycardia, and EKG abnormalities. Vascular complications are sometimes associated. They consist of thromboembolic disease, specifically, deep thrombophlebitis, intraventricular thrombi, and/or pulmonary embolism. Cardiovascular complications may evolve during 1 month and engage the vital prognosis. Death may result from embolism of the pulmonary artery or paroxysmal tachycardia. Definitive sequelae are possible.

Other complications

Digestive complications (acute necrotizing enterocolitis, massive protein exudation with hypoalbuminemia, and systemic edema) are possible (Dupouy-Camet and Bruschi, 2007). Respiratory complications (pneumonia, obstructive bronchitis, or Löffler-type infiltrates, or respiratory failures) are rare. They can occur both in the early and late stages of trichinellosis (Compton et al., 1993). Ocular complications (edema and vascular lesions within the conjunctiva, the uvea, the retina, and the optic nerve, pain when moving the eyeballs, muscle paralysis, diplopia, or a disturbed accommodation) can occur (Kociecki et al., 2014).

Clinical forms

Different clinical forms have been described in acute trichinellosis according to the severity of symptomatology and the presence or absence of complications: severe, moderately severe, benign, abortive, or asymptomatic forms (Dupouy-Camet et al., 2021).

In children, the signs and symptoms of trichinellosis are less pronounced and regress more quickly than in adults. Moreover, the frequency of complications is lower. The clinical picture is milder possibly because of lower infecting doses and a less intense allergic reaction to the larvae invasion (Ozdemir et al., 2005; Dupouy-Camet and Bruschi, 2007; Neghina et al., 2011a, b).

In pregnant women, trichinellosis can cause abortion or premature delivery (Ancelle et al., 1998). Congenital trichinellosis has not been established (Kociecka, 2000; Taybouavone et al., 2009; Bruschi and Carlier, 2013).

In immunocompromised patients, trichinellosis has rarely been described with asymptomatic, benign, and severe forms. Hypereosinophilia could be absent in these patients (Dupouy-Camet et al., 2021).

In patients with a history of previous *Trichinella* infection, a longer incubation period and milder symptomatology have been reported (Dupouy-Camet and Vallee, 2006; Dupouy-camet et al., 2016; Barluet et al., 2020). In persons who regularly eat infected meat (i.e., Inuit populations), a particular chronic diarrheal syndrome has been described and is due to the strong intestinal immune reaction; that consists of rapid expulsion of adult worms from the intestine, thus preventing the muscular phase (MacLean et al., 1989).

Chronic trichinellosis

The existence of a chronic form of trichinellosis is debated. It should not be confused with definitive neurologic and cardiovascular sequelae of trichinellosis due to complications (Dupouy-Camet and Bruschi, 2007; Dupouy-Camet et al., 2021). Chronic trichinellosis has been described as persistent symptoms (myalgia, muscle fatigue, formication, numbness, coordination disorders, conjunctivitis) 10 years after acute infection (Harms et al., 1993; Kociecka, 2000; Pielok, 2001; Kociecka et al., 2001). Tongue pain or lesion associated with the presence of *Trichinella* sp. larvae and inflammation have been reported in patients infected for at least 1 year or up to 32 years (Tande and Pritt, 2012; Ait-Ammar et al., 2021).

Diagnosis

Circumstance of diagnosis

The diagnosis is suggested by the combination of fever, periorbital or facial edema, myalgia, and high blood eosinophilia, especially if there are grouped cases. It will be confirmed on the positivity of serology (or muscle biopsy). Serology allows a more sensitive and earlier diagnosis than a biopsy (approximately 10 days after infection for western blot (wb) versus 1 month for muscle biopsy). Parasitological examination of the remains of the eaten suspected meat would confirm the diagnosis and avoid muscle biopsy.

In countries where trichinellosis is infrequent, the disease may be undiagnosed by physicians not familiar with it. Therefore, the use of specialized services is necessary to make an early specific diagnosis and to give an appropriate treatment that will make it possible to avoid complications and sequelae.

Indirect diagnostic methods

Unspecific biological markers

Unspecific biological markers can suggest the diagnosis of trichinellosis. High blood eosinophils and elevated muscle enzymes are indicative of acute infection as early as 15 days ingestion of infected meat. The blood eosinophilia is very high (often > 1 G/L) and corresponds to the circulation of the larvae. It increases up to 5 weeks and can reach 30 G/L, then it gradually decreases over

2 months. Eosinophilia is associated with hyperleukocytosis. The increase in serum muscle enzymes (creatine phosphokinase CPK, lactate dehydrogenase LDH, and aldolase) is the witness of muscle lysis caused by the presence of larvae. The serum level of these enzymes will normalize in 2 months. A discrete biological inflammatory syndrome (increased C reactive protein CRP, or rate of erythro sedimentation), and lymphopenia can be found (Dupouy-Camet and Bruschi, 2007).

A moderate hyperproteinorachia can be observed during neurotrichinellosis. High levels of troponin could be associated or not with myocarditis during trichinellosis (Lachkar et al., 2008; Barruet et al., 2020).

Serology

Serology is important for the diagnosis because it differentiates trichinellosis from influenza-like illnesses, polymyositis, or other parasitosis. Several techniques have been proposed (ELISA, indirect immunofluorescence, indirect hemagglutination, latex agglutination, wb, etc.) but few have been marketed (ELISA, wb) (Bruschi et al., 2019). In practice, ELISA is widely used in screening, and wb is used as a confirmation technique (Yera et al., 2003; Dupouy-Camet and Bruschi, 2007). ELISA using soluble or ES antigens (Ag) has good performances: sensitivity is close to 100% and specificity is around 80% (Andiva et al., 2002). Wb using the same antigens has also good performances: sensitivity and specificity are close to 100% (Yera et al., 2003). It eliminates, when ES Ag is used, ELISA cross-reactions observed with other parasitosis (anisakidosis, toxocariasis, filariasis, hepatic distomatosis, schistosomiasis...) and systemic diseases (Bruschi et al., 2019). Seroconversion usually occurs between 2 and 5 weeks after infection (Dupouy-Camet and Bruschi, 2007). But, serology can be positive 10 days after infection and a few days after the onset of clinical signs. The delay of antibody appearance in serum depends on the *Trichinella* species and the infectious dose (the lower the dose, the later the antibodies appear). Wb maybe earlier than ELISA (lower detection threshold) (Yera et al., 2003). IgG are usually detected. IgM or IgA, appearing earlier in the serum, can also be tested but not routinely. IgM and IgA evaluations are used only in research laboratories.

If negative, serology should be repeated a week later. Seroconversion or increasing serum antibody levels confirm acute infection.

Direct diagnostic methods

Direct diagnosis of trichinellosis is rarely made in humans. It consists of performing and analyzing a muscle biopsy. The biopsy is done in the deltoid, triceps, or quadriceps, then stored and transported in physiological saline. The larvae can be observed on direct examination in the fresh state after crushing between 2 glass slides (trichinoscopy) or after artificial cholorhydropeptic digestion.

Artificial digestion is the more sensitive and the reference method recommended by the European Union (European Commission, 2015). This is a microscopic examination of the digested muscle tissues obtained by the combined action of heat, hydrochloric acid, and pepsin. This last method is required to determine the parasite burden (number of larvae per gram of muscle), to highlight larvae not (yet) encapsulated, and to isolate them alive (Dupouy-Camet and Bruschi, 2007). The histological examination allows the observation of larvae within the hypertrophied striated skeletal muscle fibers, which have often lost their structure. Although muscle biopsy has an absolute specificity; it is invasive and has low sensitivity especially in the absence of digestion. Besides, its prescription poses an ethical problem, because it does not help the diagnosis until the patient has recovered (3–4 weeks after the infection) and does not provide benefit to the patient.

Viability and infectivity of the larvae can be evaluated by mouse bioassay, consisting of the inoculation of a mouse immunosuppressed by injection of cyclophosphamide with the isolated larvae and analysis of the presence of larvae in muscle 5 weeks after infection (Kapel et al., 2003).

Molecular biology allows the identification of species from isolated larvae or directly from fresh or fixed samples (Caron et al., 2020). PCR can target *Trichinella* ribosomal DNA intergenic spacer region and is followed by DNA sequencing (De Bruyne et al., 2005). Multiplex PCR targets *Trichinella* expansion segment V (ESV), and internal transcribed spacer 1 and 2 (ITS1 and ITS2) (Zarlenga et al., 1999; Pozio and La Rosa, 2003).

The parasitological examination of the stool is usually negative, but Charcot-Leyden crystals (witnesses of local hypereosinophilia) can be found and, exceptionally, adults in the first days of infection (Dupouy-Camet and Bruschi, 2007).

Artificial digestion, and molecular identification, are reserved for specialized laboratories.

Human trichinellosis diagnostic criteria

The diagnosis is based on the combination of clinical or biological signs, associated with epidemiological criteria. An algorithm can help to diagnose acute trichinellosis (Dupouy-Camet and Bruschi, 2007) (Table 2).

The presented algorithm is useful to judge the validity of an individual clinical case. European Centre for Disease Prevention and Control (ECDC) established similar criteria for case definition; however, they are more appropriate in an epidemic context (Commission Implementing Decision, 2018).

Animal testing

Parasitological examination of the remains of eaten suspected meat can confirm the diagnosis and avoid muscle biopsy. Meat should be sent for analysis in authorized veterinary services or reference laboratories on animal trichinellosis. Meat analysis makes a species diagnosis and quantifies the inoculum, which are two prognostic elements of the severity of the disease.

Table 2 Algorithm for diagnosing the probability of being infected with acute *Trichinella* in humans (Dupouy-Camet and Bruschi, 2007).

Group	Clinical or biological signs
A	• Fever • Face and periorbital edema • Myalgia
B	• Neurological signs • Cardiac signs • Conjunctivitis • Subungueal hemorrhage • Skin rashes (maculopapular rash) • Diarrhea
C	• Eosinophilia (>1G/L) and/or increased total IgE • Elevations of muscle enzymes (CPK, LDH, Aldolase)
D	• Positive serology (with a highly specific test) • Seroconversion • • Positive muscle biopsy

CPK: creatine phosphokinase, LDH: lactate dehydrogenase.

The diagnosis of trichinellosis is:

- unlikely: association of a sign A or a sign B or a sign C.
- suspect: a combination of an A sign or two B signs and a C sign.
- highly probable: a combination of three A signs and two C signs.
- certain: association of 3 signs A, two C, and a D or association of a few signs A or B, a C and a D.

Fig. 3 Muscle larva of *Trichinella* observed after compressing a muscle fragment from wild boar between two glass slides (trichinoscopy) From A. Debruyne collection, X400.

Meat analysis consists to detect the larvae by trichinoscopy (Fig. 3) or isolating the larvae after artificial digestion.

As previously mentioned (see [Direct diagnostic methods](#) section), artificial digestion is the more sensitive and the reference method recommended by the European Union (European Commission, 2015). The parasitic burden is quantified in the different animal parts (number of larvae/g of muscle). The detection threshold is 0.1–1 larva/g depending on the quantity of meat analyzed. Species identification of the isolated *Trichinella* larvae is performed after DNA extraction and multiplex PCR (Zarlenga et al., 1999; Pozio and La Rosa, 2003). The viability and infectivity of the larvae can be evaluated by mouse bioassay (Kapel et al., 2003).

Treatment

The treatment combines a benzimidazole anthelmintic, albendazole, and a systemic corticosteroid. The possibility of complications requires the rapid initiation of treatment. Therefore, it should not be delayed by waiting for serological results.

The corticosteroid is highly recommended, it prevents the occurrence of complications. Anthelmintic treatment is more effective when it is prescribed early. It is active during the intestinal phase in adult females to stop the release of larvae.

Albendazole is prescribed at 15 mg/kg/day for 10–15 days. Its intestinal absorption is favored during a fat meal. The molecule cannot be administrated during pregnancy and in children under 2 years old. Prednisone is given at 1 mg/kg/day for 1 week.

Prevention

Globally, the main source of human cases remains pork, particularly in areas where family farming is practiced without sanitary controls. Other sources of infection are game meat (wild boar, bear, warthog, reptiles, etc.) and horse meat.

Like raw meat, undercooked meat (smoked or dried meat) is at risk of transmission. Curing (salting), drying, smoking, or using the oven microwave are not efficient methods to kill the larvae.

Monitoring system

Trichinellosis is one of the zoonoses monitored by the World Organization for Animal Health (OIE). An annual report allows estimating the incidence of animal trichinellosis country by country (OIE site http://www.oie.int/fr/fr_index.htm).

In Europe, human trichinellosis is a reportable disease obligatory in the context of toxic-infections collective food (Commission Implementing Decision, 2018). During outbreaks, the search for incriminated food is essential. It allows to subtract the source of the food circuit and prevents new contaminations.

Collective prophylaxis

Pigs raised in the open air present a risk of contamination by eating the corpses of wild animals. Therefore, in Europe, they are subjected to a mandatory diagnosis of trichinellosis during slaughter (Council of the European Communities, 2004). If the above-ground pig farms do not meet obligations of controlled housing conditions, i.e., ensuring control of the risk of contamination by *Trichinella* spp., the animals must undergo a compulsory diagnosis at the slaughterhouse. All horses are diagnosed at the slaughterhouse, as well as wild boars. Game meat intended for consumption outside the private family circle must also be analyzed by a certified laboratory.

For wild boar meat, information from contamination risk is disseminated to hunting federations. Travelers should be informed of the risks of eating raw meat products bought outside of the official market (uninspected) in countries with a high prevalence of trichinellosis (Romania, Serbia, Bulgaria, China, Southeast Asia).

Individual prophylaxis

Individual prophylaxis is based on sufficient cooking of the meat. *Trichinella* larvae are destroyed by cooking at least 65 °C for 5 min. Freezing for a long time can be an alternative but temperature depends on the thickness of the meat and the *Trichinella* species.

When applied, the prevention is effective. In the United States, a significant decrease in cases was observed and was attributed to the improvement of breeding conditions for pigs (confinement) and information on consumers regarding the risks (cooking, freezing) (Wilson et al., 2015). Western European countries had a strong decrease in their numbers of cases after applying control of meat before processing and marketing (Murrell and Pozio, 2011). In 2017, 15 EU/EEA countries reported only 224 cases of trichinellosis, of which 168 cases were confirmed (European Centre for Disease Prevention and Control (ECDC), 2019).

Conclusion

In countries with efficient veterinary authorities, autochthonous trichinellosis has become a rare occurrence, usually associated with hunting or traveling. However, trichinellosis could be underdiagnosed in low-income countries with limited access to health infrastructures and even in industrialized countries where physicians are not familiar with this infrequent disease.

Introduction

Trichomonas is a genus of amitochondriate metamonads, flagellated protozoans of the Parabasilia lineage of eukaryotes, within the clade Excavata and family Trichomonadidae (Guiliano and Lamb, 2012). The flagellates typically possess four free flagella, and a fifth along the outer margin of the undulating membrane. No cysts are present (Burgess, 2005). Species that infect humans include: *Trichomonas vaginalis*, in the genitourinary tract, and *Trichomonas tenax*, in the oral cavity. Other trichomonad species that have been identified in the human lungs include: *Pentatrichomonas hominis*, a commensal in the human intestinal tract, *Tetratrichomonas gallinarum*, a parasite of the avian intestinal tract, *Tritrichomonas foetus*, a pathogen of the bovine reproductive tract. This may highlight the zoonotic potentials and the unrecognized pathogenicity of trichomonads (Duboucher et al., 2008; Kamaruddin et al., 2014).

Trichomonas vaginalis

The parasite

Historical trajectory

The parasite was discovered by Alfred François Donné, a French medical doctor and microbiologist in 1836. As the parasite combined features of the flagellate protozoan genera Tricodes and Monas, he named it Trico-monas with the species name vaginalis, but he designated that the parasite was to be found in the secretions of both male and female genitalia. In collaboration with the Parisian physicist Leon Foucault, Donné made a photomicrograph showing several protozoan parasites lying among vaginal epithelial cells (VECs). His publication of an engraved image of the photomicrograph in 1945 was a landmark in the history of photography and microbiology (Hajdu, 1998; Campbell, 2001). For long, the pathogenicity of *T. vaginalis* was questioned, and the parasite has been considered a self-cleaning female nuisance agent. It was not until the early 1930s, that attention towards *T. vaginalis* as a common cause of urogenital morbidity was redirected (Forgan, 1972).

Forms and structure

T. vaginalis exists in different cellular forms, the best characterized being the highly motile ovoid or pyriform trophozoites. The trophozoites are about $9.7 \times 7 \mu\text{m}$ and typically possess four anterior flagella, and a fifth recurrent flagellum along the edge of the undulating membrane. The flagella arise from the parabasal bodies, at the most anterior region, and emerge from the cell through the flagellar canal. The costa is a slender, striated structure at the base of the undulating membrane, that originates from the second basal body (Lee et al., 2009). The pelta-axostyle system, cytoskeletal structures, consists of microtubules that overlap anteriorly

(Benchimol, 2004). The pelta is comma shaped, surrounding the basal bodies, and reinforcing the wall of the flagellar canal. The axostyle runs along the longitudinal axis of the body, from the area of the basal bodies to the posterior end, where it protrudes as a thin tip (Ribeiro et al., 2000). The Golgi complex, the parabasal apparatus, comprises the Golgi cisternae, and the parabasal filaments, two microfibrillar striated strands linked to the basal bodies (Fig. 1) (Honigberg and Brugerolle, 1990; Benchimol et al., 2001; Lee et al., 2009). The cytostome is not conspicuous (Beaver et al., 1984). A nucleus, with one nucleolus, is at its anterior portion (Honigberg and King, 1964; Benchimol, 2004). The rough endoplasmic reticulum is clearly seen around the nucleus, and also in close association with the axostyle and the hydrogenosomes (Benchimol et al., 2000). The cytoplasm is glycogen rich, has different vacuoles including lysosomes (Costamagna and Figueroa, 2001). The hydrogenosomes, spherical double membrane organelles, are seen as paracostal and paraxostylar sets of granules (Nielsen and Nielsen, 1975; Petrin et al., 1998). Trophozoites can bind together to form large aggregates, and this clumping is displayed only by some parasite strains (Hirt, 2013; Coceres et al., 2015).

An amoeboid form, characterized by an increase in surface contact, is induced upon trophozoite contact with epithelial cells and extracellular matrix proteins (Hirt, 2013). Morphological transformation is associated with cytoskeletal protein rearrangement, that connects the tubulin based flagellar swimming with actin based amoeboid gliding (Kusdian et al., 2013). Upon unfavorable conditions; as chemical and temperature perturbations, a third cellular form, pseudocysts, have been described as rounded structures having internalized flagella (Pereira-Neves et al., 2003). In addition, cyst like structures have been demonstrated in the stationary phase of *T. vaginalis* axenic culture and in vaginal swabs from cervical neoplasia patients (Afzan and Suresh, 2012; Dias-Lopes et al., 2017). These forms have been recently reported to exhibit features similar to other parasitic protozoan cysts (Beri et al., 2020).

Genome

T. vaginalis genome is the largest of any protozoan genome currently available, with about 160 Mbp organized into 6 haploid chromosomes (Carlton et al., 2007). The original genome identified approximately 60,000 protein coding genes, which were reduced to about 46,000 after clustering identical sequences, but the genome was further estimated to reach 175 Mbp (Smith and Johnson, 2011). Differences in estimation of genome size and number of coding genes are mainly due to its repetitive nature, up to 65% appeared to consist of repetitive sequences, and an unknown amount of genome duplication events (Gould et al., 2013). Despite the large size of the genome, *T. vaginalis* lacks the entire repertoire of genes involved in glycosylphosphatidyl inositol (GPI) anchors synthesis (Carlton et al., 2007; Hirt et al., 2011). GPI is a lipid anchor for many cell surface proteins, and is used ubiquitously in eukaryotes (Kinoshita, 2016). The repetitive nature, and the large array of transposable elements, hinder a complete assembly of the genome, which still consists of thousands of individual scaffolds listed at TrichDB (Aurrecoechea et al., 2009; Kusdian and Gould, 2014).

Biology

T. vaginalis is an extracellular protozoon, with high tissue and host specificity, that resides in the complex human genitourinary environment. The parasite reproduces every 8–12 h by longitudinal binary fission. Trichomonads have one of the most primitive mitosis methods, as the spindle is extranuclear (paradesmosis) and the nuclear envelop does not fragment during the cell cycle; closed mitosis (Benchimol, 2004). The presence of meiotic specific genes in *T. vaginalis* points at the possibility of sexual reproduction (Malik et al., 2008).

T. vaginalis is an obligate parasite that lacks the ability to synthesize many macromolecules de novo, particularly purines, pyrimidines and many lipids. The parasite can phagocytose human cells including VECs and immune cells (Midlej and Benchimol, 2010). It can also phagocytose host microbiota (Pereira-Neves and Benchimol, 2007; Hirt et al., 2011). Phagocytosis provides the parasite with important sources of nutrients. Iron is an important nutrient for the parasite and a key factor in its gene regulation, and *T. vaginalis* has evolved multiple mechanisms for acquiring iron from specific iron binding, and iron containing proteins (Lehker and Alderete, 1992; Hernández et al., 2014). Iron may be obtained by hemoglobin degradation after lysis of erythrocytes (Lehker et al., 1990; Petrin et al., 1998). The parasite can also internalize lactoferrin and hemoglobin through receptor mediated endocytosis (Sutak et al., 2008).

Trichomonas is a typical anaerobe, with no oxygen requirements, but sometimes is considered as microaerophile as it grows slightly better at very low oxygen tension (Paget and Lloyd, 1990). Hydrogenosomes contain enzymes that engage in the metabolism of pyruvate formed during glycolysis and are the site of molecular hydrogen production. The process is associated with ATP synthesis (Muller et al., 2012). In the urogenital tract, *T. vaginalis* is regularly exposed to low oxygen concentration, and therefore must possess mechanisms to protect its organelles from the detrimental effects of molecular oxygen and reactive oxygen species. The parasite seems to utilize a sophisticated system to buffer oxygen stress; a combined cytosolic—hydrogenosomal antioxidant system (Coombs et al., 2004; Mentel et al., 2008).

T. vaginalis was found to establish symbiotic relationships with different microorganisms, which may affect its metabolic biochemical pathways and/or have important consequences for its virulence and pathogenicity (Fichorova et al., 2017). The parasite can harbor up to four DS-RNA viruses, members of the Totiviridae named TV virus (TVV1, TVV2, TVV3 and TVV4), closely associated with the Golgi complex (Goodman et al., 2011a). TVV may modulate parasite virulence by influencing gene expression (Orujzadeh et al., 2019). Moreover, a symbiotic association between *T. vaginalis* and *Mycoplasma hominis* has been described (Hirt et al., 2011; Dessi et al., 2019). There is also a recent discovery of a new bacterium named *Candidatus M. girerdii*, a mycoplasma within *Trichomonas* (Fettweis et al., 2014; Margarita et al., 2020).

Epidemiology

T. vaginalis is the causative agent of trichomoniasis, a disease with a high global burden being the most common non-viral sexually transmitted infection (STI) (Menezes et al., 2016; Van Gerwen and Muzny, 2019). WHO estimates of the disease rates globally in 2008, were an incidence of 276 million new cases each year, and a prevalence of 187 million infected individuals with ages between 15 and 49 years old. Data collected during the 2013–14 National Health and Nutrition Examination Survey (NHANES) in US, revealed a prevalence of 1.8% in females and 0.5% in males, aged 18–59 years (Patel et al., 2018). In 2016, WHO estimated 156 million cases of *T. vaginalis* worldwide, accounting for almost half of the global STIs incidence that year (Fig. 2) (Rowley et al., 2019).

The incidence of infection depends on several factors including age, gender, ethnicity, sexual activity, number of sexual partners, other sexually transmitted diseases, menstrual phase, hormonal contraception, diagnostic technique, social and economic conditions (Meites, 2013; Poole and McClelland, 2013). Unlike other STIs, significantly higher rates of *T. vaginalis* infections are found in older men and women compared with adolescents and younger adults (Sutton et al., 2007; Meites et al., 2015). Many sexually transmitted infections are more prevalent in women than men. Biological factors include large surface area of the female genital tract, alterations in physiology of reproductive tissues during different phases of the menstrual cycle, influence of sex hormones and hormonal contraception, and effect of indigenous microbiota (Wessels et al., 2018). Sex hormones may contribute to the variation of *T. vaginalis* acquisition and persistence and may influence the mucosal immune defense. Moreover, trichomonad movement and attachment to cells appear to be affected by the presence of estrogen, and protein containing estrogen binding sites have been identified in *T. vaginalis* (Ali and Abdul Khaliq, 2015). The prevalence in pregnant women was found to range from 3.9–24% in low to middle income countries, in Latin America and Southern Africa (Davey et al., 2016).

Infections are more common among certain racial and ethnic groups; Africans or persons of African descent have higher rates. High prevalence of infection has been also detected among incarcerated men and women, and patients at STD clinics. In US, higher rates of *T. vaginalis* infection have been reported among black, compared to man and women of other ethnicities (Sutton et al., 2007; Gaydos et al., 2013; Muzny et al., 2013). In South Africa and Australia, the parasite is more prevalent among indigenous populations (Bygott and Robson, 2013; Hillier, 2013; Naidoo and Wand, 2013). The ethnic disparity concerning *T. vaginalis* may be multifactorial, involving differences in sexual risk behaviors, and inadequate access to health care resources (Ford and Browning, 2011; Van Gerwen and Muzny, 2019). *T. vaginalis* was found significantly associated with STIs (Chlamydia, gonorrhea, Herpes simplex virus types 1&2, syphilis, and HIV), in the 2001–04 NHANES among women aging 14–49 years in the civilian, non-institutionalized US population (Allsworth et al., 2009). Among high risk women, rates range from 5% in female sex workers in Lahore in Pakistan, 9% in Yunnan Province in China, to 53% amid incarcerated women in US (Khan et al., 2011; Roth et al., 2011;

Fig. 2 Prevalence of TV infections in women and men distributed over WHO regions, 2016.

Luo et al., 2016). Among high risk men, rates range from 2% amid jail inmates in California in US, 3–17% in STI clinic attendees, to 75% among male partners of women with *T. vaginalis* in Southeast US (Schwebke and Hook, 2003; Hobbs et al., 2006; Freeman et al., 2010).

The parasite is a highly contagious protozoan with an apparently simple life cycle, consisting mainly of the trophozoite, no true cyst stage is known and contribution of pseudocysts in the parasite life cycle is not well investigated. Trophozoites are transmitted from host to host through sexual intercourse (Conrad et al., 2012). The parasite can survive outside the body for 6–24 h in urine, semen, and swimming pool water, but only up to 30 min when exposed to air (Pereira-Neves and Benchimol, 2008). *T. vaginalis* can grow over a wide range of pH values, with an optimum level between pH 6 and 6.3 (Petrin et al., 1998). Nonsexual transmission is rare but had been observed in cases involving contaminated showers, moist wash clothes, toilet seats or specula (Adu-Sarkodie, 1995; Mielczarek and Blaszkowska, 2016). Transmission is also possible via artificial insemination of infected cryobanked semen (Sherman et al., 1991; Habib et al., 2004). Neonatal infection with *T. vaginalis* is infrequently reported but has been associated with urinary tract infections and vaginitis, infection being acquired from the maternal genital tract (Trintis et al., 2010). The parasite may also play a role in multiple sites neonatal infection, including the respiratory and urinary tract, and colonization of the latter may increase the risk of developing concomitant bacterial urinary tract infection (Carter and Whithaus, 2008; Bruins et al., 2013; Kusdian and Gould, 2014).

Investigations in the molecular epidemiology of *T. vaginalis* infections have identified two distinct genome structure types, associated with clinically relevant unique phenotypes (Goodman et al., 2011a; Conrad et al., 2012). Type 1 *T. vaginalis* isolates have a higher prevalence of infection with TVV, while type 2 *T. vaginalis* isolates are marked by a higher prevalence of resistance to metronidazole (MNZ). The global distribution of Types 1 and 2 *T. vaginalis* infections has been outlined by analysis of clinical isolates from US, Mexico, Chile, Italy, South Africa, Mozambique, Australia, Papua New Guinea, and India. Types 1 and 2 *T. vaginalis* infections were found of global distribution, being detected with equal frequency in most regions, but with two notable exceptions: in isolates from South Africa and Mozambique, all samples were type 1 *T. vaginalis*, while samples from Mexico had significant higher prevalence of type 2 *T. vaginalis* infection (Conrad et al., 2012; Poole and McClelland, 2013).

Still, trichomoniasis is classified as a neglected disease. *T. vaginalis* is not a reportable infection, and there is a lack of case reporting data at national global levels (Poole and McClelland, 2013). Moreover, prevalence data are underestimated due to failure in diagnosis, as consequence of insensitive methods, or lack of testing in asymptomatic patients, and limited knowledge related to infection duration (Secor et al., 2014; Menezes et al., 2016).

Virulence factors and pathogenesis

Establishment and maintenance of infection are mediated through several mechanisms including: binding to, and degradation of elements from the mucus and extracellular matrix (ECM) proteins, binding to host cells, including VECs and immune cells, leading

to cytotoxic effects, phagocytosis of vaginal bacteria and host cells (VECs, erythrocytes, and immune cells), endocytosis of host proteins, immune evasion strategies, and interactions with the microbial community of the vagina (Fig. 3) (Hirt et al., 2007; Kusdian and Gould, 2014).

Surface membrane proteins

Surface proteins of mucosal pathogens play essential roles in initiating and sustaining the colonization of the highly defended mucosa (Hirt et al., 2007). The surface of *T. vaginalis* is covered by a highly variable coat of proteins, some proteins are found more frequently exposed on the surface of the more virulent strains than others (De Miguel et al., 2010; Noël et al., 2010; Ryan et al., 2011). A major lipid anchored phosphosaccharide, known as lipophosphoglycan of *T. vaginalis* (TVLPG), is perhaps the most abundant component of the parasite surface glycocalyx, and is an important virulence factor (Bastida-Corcuera et al., 2005; Singh et al., 2009).

The largest gene family in *T. vaginalis* encoding candidate surface proteins, is the Bacteroides surface protein A-like proteins (BspA) (Carlton et al., 2007; Hirt et al., 2007). They share a specific type of leucine rich repeats (LRRs), known as *Treponema pallidum* LRRs, and have been shown to mediate binding to host epithelial cells, and/or ECM proteins (Kobe and Kajava, 2001; Hirt et al., 2011). A group of potential surface proteins, that are classified as transmembrane proteases, includes four families: GP36-like metalloproteases, subtilisin-like, serine proteases, and calpain-like cysteine proteases (Kusdian and Gould, 2014). Among other identified parasite surface proteins are: P270, a prominent, and phenotypically variable protein (Khoshnan et al. 1994; Alderete, 1999a), Chlamydial polymorphic membrane proteins (TVPmp) (De Miguel et al., 2010), Legume-like surface lectins, may be involved in binding and endocytosis (Rendon-Maldonado et al., 2003), and tetraspanins (TVTSPs), are localized on the surface and in intracellular vesicles, have been implicated in cell adhesion, parasite migration and sensory reception during infection (Hemler, 2003; Coceres et al., 2015).

Secretion of soluble factors

T. vaginalis contact independent pathologic mechanisms comprise the secretion of a number of soluble biologically active molecules. A soluble factor released by the parasite into the medium, is a glycoprotein of 200 kDa known as cell detaching factor (CDF) (Arab-mazar and Niyiyati, 2015). CDF helps the parasite to traverse the mucus barrier of the host epithelium and promotes the release of host cells from the tissue and mucosal desquamation (Sood and Kapil, 2008; Harp and Chowdhury, 2011). The parasite secretes a wide range of hydrolases, including cysteine proteinases (CPs), that appear to be associated with parasite virulence. *Trichomonas* CPs are involved in various pathogenic processes including invasion of the mucus layer, cell adhesion, cytotoxicity, cytoskeleton disruption of erythrocytes, apoptosis of VECs, and evasion of the host immune response (Hernández

Fig. 3 TV virulence mechanisms involved in the establishment of infection and pathogenesis. BspA, bacteroides surface protein A-like; ELVs, exosome-like vesicles; LPG, lipophosphoglycan; SALIPs, saposin-like proteins; TSPs, tetraspanins; VECs, vaginal epithelial cells.

et al., 2014). The synthesis and proteolytic activity of certain CPs are regulated by environmental factors, such as iron, pH, temperature, and polyamines (Carvajal-Gamez et al., 2014).

A set of soluble proteins, that are reported to be secreted and act as adhesion molecules, include heat shock proteins (HSP), and metabolizing enzymes of the hydrogenosome (Kusdian and Gould, 2014). *T. vaginalis* produces several cytotoxic molecules, including pore forming proteins, members of a conserved family of saposin-like proteins (SAPLIPs). *T. vaginalis* SAPLIPs (trichopores) contribute to cell lysis, and death by forming transmembrane channels, in the lipid membrane of target cells, leading to osmotic lysis (Ojcius and Young, 1991; Fiori et al., 1996; Menezes et al., 2016). Moreover, lytic factors with phospholipase A-like activity, that destroy nucleated cells and erythrocytes, have been described (Hirt, 2013). *T. vaginalis* was found to secrete exosome-like microvesicles. *T. vaginalis* exosomes are about 50–100 nm in diameter and contain a large diversity of proteins and RNA (Twu et al., 2013). Exosomes fuse with, and deliver their contents to the host cell, and can modulate the host immune reactions. The proteome of the exosomes appears to differ according to the strain, as exosomes of a highly infectious strain increased the binding efficiency to host tissues of a less adherent strain (Kusdian and Gould, 2014).

Trichomonas morphogenesis and cytoadherence

An essential step of the infection process is the rapid transformation of *T. vaginalis*, from the flagellated to an adherent amoeboid cell. Upregulation of actin and actin associated genes occurs, while α -actinin is distributed throughout the cytoplasm in the flagellate, the protein localizes at the parasite periphery in the amoeboid form (Gould et al., 2013; Menezes et al., 2016). The speed with which the transformation occurs, few minutes upon exposure to VECs, is unique. The flagella and costa are not degraded during morphogenesis and attached cells can rapidly detach again and change location. Parasite morphogenesis comprises at least two distinct, but simultaneous processes: shape transition, and adherence to host cells (Kusdian and Gould, 2014).

Contact dependent mechanisms play a crucial role in host cell destruction. The parasite can cross the mucus layer of the genital tract by binding to mucin, followed by its proteolytic degradation by the parasite mucinase; thus, reaching the underlying epithelium (Hernández et al., 2014). Adhesion of *T. vaginalis* to epithelial cells is mediated by numerous adhesions. The parasite expresses LPG at several million copies per parasite, anchored on the surface by an inositol phosphoceramide (Singh, 1993; Singh et al., 1994). TVLPG binds to galectin-1 and -3 receptors in the host cells, playing a role in adherence, and cytotoxicity to VECs. It can also modulate the inflammatory responses of epithelial cells and macrophages (Fichorova et al., 2006, 2016; Okumura et al., 2008). Although the binding of LPG-receptor may be central in establishing the infection, *T. vaginalis* involves other adhesion factors to implement the host-parasite interactions (Hirt et al., 2007).

Parasite interaction with vaginal microbiota and endosymbionts

T. vaginalis interaction with the genital microflora is complex. The parasite may modulate and induce imbalance in the vaginal microbial community, leading to dysbiosis with reduction of the protective Lactobacilli (Brotman et al., 2012). TVLPG ceramide phosphoinositol glycan core, cooperates with pathogenic vaginal bacteria to alter bacterial colonization patterns, and the local immune environment in support of bacterial vaginosis, which in turn facilitates parasite survival (Fichorova et al., 2013). The vagina of the reproductive age women is characterized by the presence of a complex population of aerobic and anaerobic microorganisms that has been classified into five community state types (CSTs); four of these CSTs are dominated by the protective Lactobacilli. While one type (CST-IV) has anaerobic bacteria and no Lactobacilli. CST-IV are the causative agents of bacterial vaginosis, as they induce physical, immunological, and biochemical changes in the cervicovaginal mucosa, promoting a greater proinflammatory response in the vagina than the Lactobacilli-dominant communities (Mitchell and Marrazzo, 2014; Amabebe and Anumba, 2018). Lactobacilli exert its protective effect by lowering vaginal pH through lactic acid and by competing for nutrients. Moreover, the presence of Lactobacilli was found to inhibit *T. vaginalis* adhesion (Phukan et al., 2013). The low abundance of Lactobacilli associated with trichomoniasis creates a more basic milieu, more favorable for parasite growth and pathogenicity (Petrin et al., 1998). Parasite active feeding of the host microbiota may cause in addition the acquisition of a number of bacterial genes through gene transfer, that modulates its virulence. A complete set of bacterial enzymes capable of degrading glycans, and mostly acquired from the Bacteroides group, have been identified (Alsmark et al., 2013; Hirt, 2013). *T. vaginalis* cooperation with pathogenic vaginal bacteria, was found to enhance the paracellular permeability of the genital tract epithelium by disturbing the integrity of the tight junction complex (Hinderfeld et al., 2019).

The presence of *Trichomonas* endosymbionts may enhance its pathogenic effect and modify the host immune response (Margarita et al., 2020). In Europe, up to 90% of *T. vaginalis* strains are naturally infected with *M. hominis* (Fürnkranz et al., 2018). The parasite-Mycoplasma symbiosis could interfere with production of the antimicrobial NO by human macrophages, through outcompeting for the key substrate arginine (Das et al., 2010; Gogoi et al., 2016; Margarita et al., 2016). The role of TVV in the pathogenesis of trichomoniasis is still not well clarified. The virus has been observed to alter cell surface expression of P270, a highly immunogenic protein, and CP expression profile. This may suggest that the virus impairs the clearance of the infection, and predisposes to its longer persistence (Alderete et al., 1986; Provenzano et al., 1997; Goodman et al., 2011b).

Clinical features

T. vaginalis infection results in a variety of clinical manifestations. Studies have revealed that around 80% of infections are asymptomatic in both men and women (Sutton et al., 2007; Allsworth et al., 2009; Menezes et al., 2016). However, even asymptomatic infections are a public health concern, due to the risk of transmission to sex partners, and the pathologic sequelae of the infection (Poole and McClelland, 2013).

In women, symptoms may appear after an incubation period of 4–28 days, however, this period is not clearly known, and about one third of women become symptomatic within 6 months (Petrin et al., 1998; Menezes et al., 2016). The main complaints are vaginal discharge, odor, pruritis, dysuria and dyspareunia (Muzny and Schwebke, 2013). Although the discharge is typically described as being frothy yellow or green in color; the aspect and consistency are widely variable among patients (Schwebke and Burgess, 2004; Swygard et al., 2004). The vagina and cervix may be erythematous and edematous, and punctate hemorrhagic spots may be found on the mucosa; strawberry cervix. This clinical sign is the most indicative of the disease, still it is clinically diagnosed only in 2–5% of women (Lehker and Alderete, 2000).

The extent of the inflammatory response to the parasite may determine the severity of symptoms. Factors influencing the host inflammatory responses include hormonal loads, coexisting vaginal flora, and the strain and relative concentration of the parasite in the vagina (Schwebke and Burgess, 2004). Trichomoniasis symptoms are cyclic and more intense around the menstrual period; as it has been suggested that the iron rich environment of the vagina in menstruating women enhances *T. vaginalis* growth and persistence (Petrin et al., 1998).

In men, the natural history and the spectrum of the disease are less well characterized as the infection is commonly self-limited and transient (Hirt and Sherrad, 2015; Menezes et al., 2016). The oxidative nature of the male genital fluid and the zinc rich environment of the prostate may inhibit persistent infection (Figuerola-Angulo et al., 2012; Gimenes et al., 2014). The mean incubation period in men is approximately 10 days (Poole and McClelland, 2013). Manifestations include urethritis accompanied by scanty, clear to mucopurulent discharge, dysuria and mild pruritis or burning sensation immediately after sexual intercourse (Petrin et al., 1998; Menezes et al., 2016).

Pathologic sequelae

In women, the parasite can persist for long periods in the urogenital tract. Untreated or persistent *T. vaginalis* infection has been implicated in adverse birth outcomes and infertility (Van Gerwen and Muzny, 2019). In pregnant women, infection has been associated with preterm rupture of membranes, preterm delivery, low birth weight neonates, and cases of neonatal vaginal and respiratory infections (Cram et al., 2002; Simhan et al., 2005; Carter and Whithaus, 2008; Silver et al., 2014). Preterm birth may be caused by the parasite modulating the human innate immune responses including proinflammatory cascades and mucosal inflammation (Mercer and Johnson, 2018). A compromised cervical epithelial barrier can promote cervical remodeling which is an initial step towards preterm birth (Timmons et al., 2010; Hinderfeld et al., 2019). Moreover, cytokines (IL-1 β , IL-6) and prostaglandins (PGE2, PGE2a) which are released in response to *T. vaginalis* infection can induce uterine contractions increasing the risk of preterm birth (Cram et al., 2002).

T. vaginalis has been linked to infertility, pelvic inflammatory disease (PID) and cervical neoplasia. It is more often reported in infertile women than in control subjects and is probably associated with cervical and tubal factor of infertility (El-Shazly et al., 2001; Soper, 2004; Roh et al., 2015). PID is the infection and inflammation of upper genital tract structures caused by ascending microorganisms from the lower genital tract. PID can lead to infertility, ectopic pregnancy or chronic pelvic pain (Wiringa et al., 2020). There is a growing body of evidence that *T. vaginalis* may play a role in the pathogenesis of PID (Moodley et al., 2002; Cherpès et al., 2006; Reighard et al., 2011; Wiringa et al., 2020). Different studies have demonstrated that infected individuals have a higher risk of cervical cancer; especially in cases co-infected with Human Papilloma virus (Verteramo et al., 2009; Lazenby et al., 2014; Yang et al., 2018). A remarkable health outcome of *T. vaginalis* infection is its positive relation with both transmission and acquisition of HIV (Menezes et al., 2016). *T. vaginalis* screening among HIV infected women in US revealed high prevalence (17.4–20%), and repeated infection rates up to 22.7% over a median of 16 months (Muzny et al., 2019). The main mechanisms by which the parasite may enhance HIV acquisition include mucosal microhemorrhages that compromise the epithelial barrier, the local inflammatory response and recruitment of immune cells including HIV target cells as CD4⁺ and macrophages to which the virus can bind and gain access, and by increasing susceptibility to bacterial vaginosis or persistence of abnormal vaginal flora (Moodley et al., 2002; Shafir et al., 2009; Quinlivan et al., 2012; Kissinger and Adamski, 2013). Endocytosis of the virus and its accumulation in endosomal-like structures, might contribute to transmission when the parasite is transferred from dually infected patients to new hosts (Pindak et al., 1989; Rendon-Maldonado et al., 2003; Lal et al., 2006; Hirt et al., 2011).

In men, sequelae of infection include prostatitis, balanoposthitis, epididymo-orchitis and infertility, possibly through chronic inflammation and cell lysis (Menezes et al., 2016). Moreover, the parasite can decrease both sperm motility and viability (Martinez-Garcia et al., 1996; Kissinger, 2014). *T. vaginalis* has been associated with a risk of cancer prostate development; possible mechanisms include its prostatic tropism, ability to elicit inflammation and damage to the prostatic epithelium, its tendency to cause chronic subclinical infections, altering polyamine levels, and upregulation of expression of anti-apoptotic and other proto-oncogenes (Sutcliffe, 2010; Marous et al., 2017). A *T. vaginalis* homologue of the inflammatory cytokine, macrophage migration inhibitory factor (TVMIF), has been suggested as a contributor to prostate cell growth and invasiveness (Twu et al., 2014; Menezes et al., 2016).

Immunity in trichomoniasis

Trichomoniasis does not produce an effective permanent immunity; this may lead to recurrent infections. Consequently, the innate immune responses become crucial for infection control (Menezes et al., 2016). Moreover, the quality of the adaptive immune responses, is probably influenced by concomitant microbial infections and symbionts and may be further complicated by parasite lysis of effector immune cells (Mercer et al., 2016).

The non-specific defense mechanisms against the parasite include activation of the alternative pathway of the complement system, which provides C3 opsonin that promotes neutrophil mediated phagocytosis of *T. vaginalis* (Shaio et al., 1991). Cervical mucus is deficient in complement, the menstrual blood is the only source of complement in the vagina. Although its activity is about half that of the venous blood, menstrual blood has considerable complement mediated cytotoxicity towards *T. vaginalis*. Consequences of iron level increase during menses, upregulation of CPs expression occurs; and the proteolytic activity assists in trichomonal infection persistence after menses (Demes et al., 1988; Alderete et al., 1995; Arab-mazar and Niyiyati, 2015).

Upon binding of the parasite to host cells, activation of Toll-like receptors (TLR2, TLR4, TLR9) in epithelial cells occurs, and proinflammatory cytokines and chemokines (IL-6, IL-8, and macrophage inflammatory protein MIP-3 α) become upregulated triggering inflammation (Behzadi and Behzadi, 2016; Nemati et al., 2018). Neutrophils are the predominant immune cells recruited at the site of infection, mediating the initial inflammatory response to an acute *T. vaginalis* infection. IL-8 acts as a powerful chemoattractant for neutrophils (Escario et al., 2010; Nemati et al., 2018). Neutrophils participate in parasite killing through production of reactive oxygen species (ROS) and antimicrobial peptides (AMPs) as defensins and the lipid mediator leukotriene LTB4. *T. vaginalis* can secrete LTB4 (TVLTB4) that contributes to neutrophil chemotaxis; the TVLTB4—neutrophil/mast cells—IL-8 axis is thought to share in the mucosal inflammation that occurs during trichomoniasis (Nam et al., 2011, 2012; Le Bel et al., 2014). Monocyte derived macrophages also generate the proinflammatory cytokines (IL-1 β , IL-6, IL-8, TNF- α) in response to infection. Macrophages enrollment is an important constituent of host defense against genitourinary trichomoniasis (Han et al., 2009). Parasite stimulation of macrophages leads to expression of inducible nitric oxide (NO) synthase and NO production (Park et al., 1997).

In trichomoniasis, CD4⁺ T-helper cells interplay may lead to parasite elimination, persistence or pathological events (Nemati et al., 2018). The infection was found to induce vaginal CD4⁺ T cell infiltration in experimental infection (Smith and Garber, 2015). Upon stimulation and activation, naïve CD4⁺ T cells differentiate into separate subsets including T helper cells Th1, Th2, Th17, Th22 (regulatory T cells); each with its own cytokine profile (Zhang et al., 2014; Schmitt and Ueno, 2015). Th1 cells trigger cell mediated immunity through production of cytokines; such as INF- γ , TNF- α and IL-2, that lead to activation of the effector leucocytes; macrophages, cytotoxic lymphocytes, and natural killer cells (Nemati et al., 2018). Th1 cell related cytokines (INF- γ , IL-2) have been reported to be significantly high in the serum and vaginal secretion of mice infected with isolates from asymptomatic women as compared to mice infected with isolates from symptomatic patients. Th1 cytokines have been suggested to promote low burden infection (Malla et al., 2007). Th17 cells secrete a number of cytokines and chemokines including IL-17, with controversial reports regarding their role in trichomoniasis (Makinde et al., 2013; Masson et al., 2015). A prominent function of IL-17, is the induction of neutrophil chemotaxis at the inflammation site (Isailovic et al., 2015; Nemati et al., 2018). Th22 cells release IL-22 and TNF- α , together with IL-17 they synergistically upregulate production of AMPs, defensins and LL-37; the sole member of the cathelicidin family (Kahlenberg and Kaplan, 2013; Dempsey, 2017; Eyerich et al., 2017). Elevated levels of IL-22 and LL-37 were reported in vaginal secretions from *T. vaginalis* infected women as compared to uninfected, and IL-22 has been assumed as a protective immune factor against the infection (Makinde et al., 2013).

Antibody mediated immunity in trichomoniasis has been reported to be short lived and its role in parasite elimination and protection is unclear. Parasite specific IgG, IgM, IgA antibodies have been demonstrated by several techniques (Menezes and Tasca, 2016). LPG is one of the most commonly recognized antigens by serum samples of *T. vaginalis* infected women, in which levels of LPG specific IgA in vaginal secretions were higher than in control subjects. Also, LPG specific IgG was higher in infected women with normal pregnancy than in those with adverse pregnancy sequelae. The vaginal LPG specific IgG may be protective against adverse pregnancy outcome (Bastida-Corcuera et al., 2013; Menezes and Tasca, 2016; Nemati et al., 2018).

T. vaginalis has acquired several strategies to evade the host immune response. Parasite CPs with their high proteolytic activity can degrade host immunoglobulins, helping the parasite to survive the antibody response (Hernández et al., 2014). They can degrade C3 portion of complement on the surface of the parasite, evading complement mediated lysis. *T. vaginalis* association with the host protein CD59, a complement lysis restricting factor, may be another mechanism by which the parasite resist complement attack (Ibáñez-Escribano et al., 2015). CPs can also break down the secretory leucocyte protease inhibitor (SLPI), a factor protecting the mucosal surface of the vagina (Al-Mohammed and Hussein, 2006). Moreover, TVLPG was found to suppress the expression of SLPI by vaginal and cervical epithelial cells (Huppert et al., 2013).

Molecular mimicry is another mechanism by which the parasite can escape the host immune response. *T. vaginalis* adhesins (AP33, AP51, AP65) share immunological similarities with host metabolic enzymes and plasma proteins. The parasite can also coat its surface with molecules homologous to host proteins; avoiding being recognized by the host immune system (Figueroa-Angulo et al., 2012). The parasite challenges the immune system by displaying strain variation; including antigenic phenotypic and genetic variation (Nemati et al., 2018). P230 and P270 surface antigens are involved in parasite phenotypic variation; the former goes through conformational changes, preventing its accessibility and antibody binding, while the later surface expression is dependent on TVV endosymbiosis and iron concentration (Alderete, 1999b). A high degree of genetic diversity in *T. vaginalis* isolates has been reported using different genotyping techniques (Meade and Carlton, 2013).

Zinc assists in antimicrobial defense in the male lower genital tract. Studies have revealed the variation in zinc sensitivity between different parasite isolates; as well as variation in the zinc content of the male prostatic secretions (Krieger and Rein, 1982). These variations can induce differential expression of the parasitic proteins and affect parasite survival in the male genitourinary tract (Vazquez-Carrillo et al., 2011; Menezes and Tasca, 2016).

T. vaginalis can modulate the host immune response by stimulating the production of anti-inflammatory cytokines (IL-10, TGF- β) from macrophages and dendritic cells, which can contribute to infection persistence. *T. vaginalis* exosome-like vesicles (TV-ELVs)

increase the expression of IL-10 in macrophages (Olmos-Ortiz et al., 2017). Moreover, the parasite can reduce the expression of Th1 proinflammatory cytokines (TNF- α , IL-12) by suppressing the transcription factor NF- κ B activation; which is found to be dependent on parasite burden. Hence, interfering with cell differentiation, inflammation and apoptosis and subsequently effective Th1 cell mediated response (Chang et al., 2004; Quan et al., 2017).

Diagnosis

Laboratory diagnosis is required when trichomoniasis is clinically suspected; the diagnostic yield is mostly dependent on sample collection and type of test used (Garber, 2005). Specimens are mainly obtained from vaginal discharge, swabs from posterior fornix, and cervical smear in females, while in males from urethral discharge ideally collected before first-voided morning urine or prostatic secretions (Garber, 2005; Fernando et al., 2011). In settings where clinical genital examination is limited or unwanted, first catch urine sample and self-collected vaginal swabs could be used as well but are proved to be less effective (Mohamed et al., 2001; Karaman et al., 2008; Domeika et al., 2010; Hobbs and Seña, 2013).

Traditionally, direct wet mount preparation and microscopic observation of motile trophozoites is the widely used method, especially in field as well as in low and middle income countries (Darani et al., 2010; Adjei et al., 2019). Wet mount technique is simple, rapid, inexpensive, specific but suffers from a major drawback of being of low sensitivity, which was described to range from 30%–80%; where negative examination cannot exclude *T. vaginalis* infection (Darani et al., 2010; Fernando et al., 2011; Adjei et al., 2019). This limitation is attributed to various factors; the size of inoculum as $<10^4$ organisms/mL will not be detected, the viability of the protozoa and the need to remain moist in sample, in addition to the experience of the microscopist. Therefore, sample should be immediately examined after collection otherwise the motility will be significantly reduced or lost, making it difficult to distinguish the trophozoites from the nuclei of vaginal epithelial cells (Garber, 2005; Adjei et al., 2019). In an attempt to overcome these problems, transport media containing 5% glucose solution as energy source were used to prolong the organism viability for up to 24 h (Fernando et al., 2011). Staining techniques; such as Giemsa, acridine orange and periodic acid-Schiff, were introduced as well to improve the sensitivity of direct microscopic examination. However, their usefulness was questioned as reports revealed no increase in sensitivity in comparison to unstained wet mount smears (Garber, 2005; Adjei et al., 2019). Also, Papanicolaou smear was considered as it is routinely used in screening of variety of cervical lesions. However, the technique was indicated to be ineffective for *T. vaginalis* detection, showing poor sensitivity and specificity (Aslan et al., 2005; Hezarjaribi et al., 2015). Leukorrhea, raised vaginal pH often >6 in florid infection, and positive whiff test are findings in vaginal discharge that could be correlated to trichomoniasis (Garber, 2005; Muzny et al., 2014).

Culture is another parasitological technique; it is considered the “gold standard” for the diagnosis of *T. vaginalis*, with higher sensitivity and specificity when compared to wet mount (Darani et al., 2010; Muzny et al., 2014). Culture is especially valuable when the inoculum amount is small, depending on the type of the medium used, counts as few as 10 organisms/mL can be detected (Fernando et al., 2011; Patil et al., 2012; Adjei et al., 2019). The commonly used culture media are the standard broth Diamond’s TYI medium and the InPouch *T. vaginalis* culture. The latter offers many advantages over other culture media; it is of lower cost, stable with shelf-life of 6 months, used for sample transport and culture, furthermore the microscopic examination is done directly on the pouch itself; saving time and reducing contamination (Gallion et al., 2009; Patil et al., 2012). However, culture procedure was categorized as moderately complex, time consuming requiring 2–7 days of incubation, expensive, not readily available in field laboratories, and reliant on presence of viable *T. vaginalis* and maintenance in microaerophilic condition (Darani et al., 2010; Patil et al., 2012; Muzny et al., 2014).

Immunodiagnostic techniques based on antigen detection are alternatives to microscopy for detection of *T. vaginalis*, including rapid antigen tests; as latex agglutination and lateral flow, in addition to ELISA and immunofluorescence. Each test differs in the type of targeted antigen and has its own advantages and limitations regarding performance, cost and ease of use. The overall sensitivity and specificity of these tests were described to be higher than wet mount and comparable to culture (Darani et al., 2010; Domeika et al., 2010; Adjei et al., 2019). A number of antibody detection tests were described in the past; yet they have low sensitivity and specificity and subject to cross-reactivity (Domeika et al., 2010).

Nucleic acid amplification tests (NAATs) emerged as powerful diagnostic tools of high sensitivity and specificity surpassing those of culture techniques, plus providing the ability to detect nonviable organisms. A variety of amplification technologies and sets of primers were validated for use in *T. vaginalis* infection on multiple specimen types. These procedures can be conducted on the same testing platforms for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* (Wendel et al., 2002; Patil et al., 2012; Muzny et al., 2014). NAATs are useful and crucial in situations where low parasite density is expected as in asymptomatic individuals and those at risk of infection. Also, they perform well with non-invasive specimens as urine samples and self-collected vaginal swabs (Van Der Pol, 2016).

Treatment and prevention schemes

Trichomoniasis in females is not a self-clearing infection, and chronic infections may be maintained indefinitely. While in males, infection is usually resolved without treatment, but there is argument concerning the duration of infection (Cudmore and Garber, 2010).

Oral MNZ (α - β -hydroxyethyl-2-methyl-5 nitroimidazole; Flagyl) remains the standard treatment for trichomoniasis (Bouchemal et al., 2017). In the case of drug resistance and allergy, treatment alternatives are limited (Muzny and Schwabke,

2013). MNZ and tinidazole; 5-nitroimidazole agents, can cure *T. vaginalis*. Systemic treatment is preferred over topical applications to reach proper drug concentrations in non vaginal sites, as urethra, Bartholin's, and periurethral glands. Cure rate for single oral 2 g MNZ dose, is 90% to 95%, while tinidazole goes towards 100% cure rate (Coleman et al., 2013). Tinidazole has better pharmacokinetics for *T. vaginalis*; lower minimum lethal concentration (MLC), long half-life and higher tissue concentration (Wood and Monro, 1975; Sobel et al., 2001). MNZ targets the metabolic pathway of the hydrogenosome, where it is incorporated by passive infusion and subsequently activated. The activation generates nitro-radicals that are toxic to the parasite, by interfering with proteins and protein trafficking (Kusdian and Gould, 2014).

MNZ resistance is estimated to occur in 2.5–5% of *T. vaginalis* cases (Muzny and Schwebke, 2013). The mechanism of MNZ resistance is assumed to be due to multiple mutations (Paulish-Miller et al., 2014). In anaerobic resistance, there is a decrease in the activity of the pyruvate-ferredoxin oxidoreductase (PFOR) activity, whereas in aerobic resistance the transcription of the ferredoxin gene is reduced (Yarlett et al., 1987; Kulda, 1999; Leitsch et al., 2014; Bouchemal et al., 2017). MNZ resistance has been reported to be relative, increasing the dose or shifting to tinidazole can usually overcome the resistance (Coleman et al., 2013). However, higher doses may be associated with significant gastrointestinal adverse effects and challenging in patients who do not respond (Muzny and Schwebke, 2013).

Drugs that have been investigated as alternatives to 5-nitroimidazoles; albendazole/mebendazole (Sears and O'Hare, 1988; Oxberry et al., 1994), nitazoxanide (Dan and Sobel, 2007), have limited antiparasitic outcome (Muzny and Schwebke, 2013). Topically applied treatments are restricted to adjunctive therapy or particular cases of allergy or resistance. The use of vaginally applied anti-*T. vaginalis* thermosensitive and mucoadhesive formulations was recently described with improved residence time (Pradines et al., 2015; Bouchemal et al., 2017; Grisin et al., 2017).

Problems with current treatment and prevention strategies lead to limited success in controlling the incidence of the disease especially among the disadvantaged. *T. vaginalis* infection is usually asymptomatic and so is not treated, creating and maintaining reservoirs of infection. Moreover, most cases occur in developing countries, where healthcare facilities are restricted, allowing infection to spread within the community (Cudmore and Garber, 2010). Education concerning STIs and healthy sexual lifestyles can reduce infection incidence. Simultaneous treatment of sexual partners is recommended to prevent reinfection. Condoms use is still the best and most reliable protection means against STIs. Discomfort, religious and cultural rationales may hinder condoms use (Bouchemal et al., 2017). Female partners of circumcised males are reported to be at reduced risk of *T. vaginalis* infection (Sobngwi-Tambekou et al., 2009). However, different conclusions have been declared regarding its protective effect (Turner et al., 2008; Mehta et al., 2009). Another means of prevention is self-administration of vaginal microbicides before intercourse, which may limit parasite interaction with host cells (Lushbaugh et al., 2000).

Vaccination against *T. vaginalis* could provide long term protection, prevent health consequences, reduce medical costs and disease rates. The presence of a good animal model of *T. vaginalis* infection can help clarifying the specific elements needed to induce a strong and protective immune response required for an efficient vaccine (Cudmore and Garber, 2010). Vaccination could target high risk individuals, to protect themselves and their partners. However, the main challenges for the development of a vaccine are strain variation, parasite immune evasion strategies and transient specific humoral immune responses (Nemati et al., 2018).

Trichomonas tenax

Trichomonas tenax (*T. tenax*) was discovered and first described by the Danish naturalist Otto Friedrich Müller in 1773, who observed a flagellate in a culture of tartar from the teeth and named it *Cercaria tenax*. Thereafter, uncertainty and disagreement existed concerning the proper name of the parasite found in the human mouth. It is the English protozoologist, Clifford Dobell, in 1939, who has contributed the parasite discovery to O.F. Müller. Dobell reported that Müller's description of a pear-shaped organism in the human mouth, was the first record of the infection, and that instead of the name *Trichomonas buccalis*, *T. tenax* is the correct name (Dobell, 1939; Théodoridès and Rousset, 1980).

T. tenax is a pyriform flagellate, smaller and more slender than *T. vaginalis*, with average length of 7 µm. Morphologic differentiation from *T. vaginalis* includes: the undulating membrane is relatively longer over 2/3 of the length of the body, a thicker axostyle that extends as a sharp structure a considerable distance behind the body, a cytostome near the anterior end of the side opposite the undulating membrane (Beaver et al., 1984). *T. tenax* is an anaerobic commensal of the human oral cavity that is also colonized by other specific bacteria, fungi and protozoa (Mehr et al., 2015). The occurrence is depending on oral health status, being highly reported in those with coated tongue, dental calculus, and poorly maintained periodontal tissue (Bracamonte-Wolf et al., 2019). The level of oral contamination ranges from 4% to 53%. It survives in the mouth feeding predominantly on local microorganisms (Mallat et al., 2004).

The parasite is transmitted mainly by saliva through kissing and droplet spray and use of contaminated dishes and drinking glasses (Osborne et al., 1984; Hersh, 1985; Mallat et al., 2004). Although *T. tenax* is regarded as a human specific parasite, it has been reported to inhabit the oral cavity of different domesticated animals, raising its importance as a potential zoonotic infection (Maritz et al., 2014; Ribeiro et al., 2015; Dybicz et al., 2018a).

The flagellate has been linked to the occurrence and/or severity of periodontitis, a multifactorial inflammatory dental disease, affecting the soft tissue and bone of the periodontium (El Sibaei et al., 2012; Benabdelkader et al., 2019). Dysbiosis of the oral microbial communities takes place, with degradation of the tissue supporting the teeth, which may lead to teeth loss (Bisson et al., 2019; Dubar et al., 2020). The role of *T. tenax* in the pathogenesis of the oral disease, and the mechanisms involved in tissue damage

are still obscure (Bracamonte-Wolf et al., 2019). High parasite proteolytic activity, especially collagenolytic activity, has been demonstrated (El Sibaei et al., 2012; Dybicz, et al., 2018b). Genotyping revealed the presence of strain variability, and different strains with diverse pathogenic potential may exist (El Sibaei et al., 2012; Benabdelkader et al., 2019).

T. tenax has been detected in infections outside the oral cavity; in salivary duct infection of the submaxillary gland (Duboucher et al., 1995), in cervical adenopathy (Duboucher et al., 2000), in cerebrospinal fluid samples of patients with polymicrobial meningitis (Masur et al., 1976), in sputum samples of immunocompromised patients with chronic lung disease and in pleural empyema samples (Mahmoud and Rahman, 2004). Pulmonary *T. tenax* infection is usually caused by aspiration from the oropharynx and usually reported in patients with underlying lung disease (Hersh, 1985; Mallat et al., 2004).

Glossary

Achalasia A neuromuscular dysfunction on the esophagus characterized by swallowing difficulties.

Chagoma A hardened skin lesion, nodule or swelling at the inoculation (bite) area of the parasite (*T. cruzi*)

Enzyme immunoassay (EIA) An *in vitro* technique that applies a passive agglutination process to observe and quantify antigens.

Enzyme Linked Immunosorbent Assays (ELISA) An enzyme immunoassay used to quantify antibodies, antigens, and proteins.

Fecaloma A hardened fecal mass in the rectum or sigmoid colon.

Immunoblot (TESA) A technique used in molecular biology to identify certain proteins in a process that consist in denaturation and electrophoresis.

Indirect hemagglutination (IHA) A serological analysis that detects specific antibodies raised in response to an infection

Reservoir The reservoir is the habitat (can be humans, animals, or the environment) in which the infectious agent is conserved (can live, grow, and multiply), enabling the persistence of the transmission cycle.

Romana's sign Unilateral periorbital edema resulting observed after *T. cruzi* inoculation (1-2 weeks).

Volvulus A bowel obstruction that results from intestine twisting around itself.

Introduction

The *Trypanosoma cruzi*, the causative agent of a neglected tropical disease, the Chagas disease (CD) was first uncovered by the Brazilian physician and researcher Carlos Chagas in April 14th, 1909, in the city of Lassance, state of Minas Gerais in Brazil (Kropf and Sá, 2009). It is currently estimated that CD affects about 6-7 million people (WHO, 2020), representing a major global public health problem with significant socioeconomic impact (Lee et al., 2013; Lidani et al., 2019). In the last decades, many cases of CD have been identified in classically non-endemic regions including Europe, North America, and the Western Pacific area, where the transmission mainly occurs via blood transfusions or organ transplantation (Tarleton et al., 2014; Angheben et al., 2015).

More than a century since its discovery, CD still represents a life-threatening illness with a broad range of symptoms. The acute phase usually is asymptomatic, however, individuals chronically infected may present lower quality of life (Sousa et al., 2015), loss of productivity and even sudden death (Nunes et al., 2018) due to the CD symptomatic forms and/or associated comorbidities (Teixeira et al., 2011; Lee et al., 2013). To call international attention to CD, in 2019, the World Health Organization established the April 14th as the World Day for Chagas Disease (WHO, 2019).

Biology of *Trypanosoma cruzi*

Morphological aspects

T. cruzi, a hemoflagellate protozoan parasite, belongs to the Kinetoplastida Order, Family Trypanosomatidae (Fig. 1A). The presence of a flagellum and a particular region in mitochondria, the kinetoplast, which localizes a complex and unique mitochondrial DNA (kDNA), determine systematic morphological characteristics (Kaufer et al., 2017). The life cycle of *T. cruzi* involves invertebrate and vertebrate hosts, where different morphological forms occur during development (Contreras et al., 2002; de Souza, 2009).

In the **epimastigotes** (Fig. 1B and C), the kinetoplast is located in the central region of the body, anterior to the nucleus. The flagellum emerges from the central portion of the parasite and forms a short undulating membrane. Epimastigotes have elongated shape (20-40 µm long, 2-5 µm wide) and are less mobile than trypomastigotes. When vectors feed on the blood of the infected vertebrate, they ingest blood with trypomastigotes. These trypomastigotes pass from the salivary glands to the insect intestine, where they differ into epimastigotes by metacyclogenesis, multiplying through binary fission. After replication, they migrate to the terminal portion of the intestine, where they differentiate into metacyclic trypomastigotes.

In the **trypomastigotes** (Fig. 1D and E), the kinetoplast is in the posterior position in relation to the nucleus, usually in the terminal portion of the body. The flagellum emerges from the posterior portion and runs through the entire body of the parasite. The adhesion of the flagellum to the parasite's surface forms an undulating membrane until the anterior portion where the flagellum is free. The undulating membrane improves movement and facilitates the mobility of the protozoan. Trypomastigotes can be found in the digestive tract of the vector insect and human blood. They are infective life forms and present high resistance to different environments. The **metacyclic trypomastigotes** are those from the gut of vectors and responsible for human infection. Its body extends about 25 µm long and 2 µm wide. After the metacyclic trypomastigotes cross the skin, they travel briefly through the bloodstream and then localize in different tissues, but preferably muscle, hepatic, and nerve tissues.

T. cruzi **amastigotes** (Fig. 1F and G) are spherical (2-7 µm) and do not have prominent flagella outside of the body. The kinetoplast is close to the nucleus. Amastigotes are not mobile and are replicative/proliferative forms in the intracellular environment of the vertebrate host. The process of cell division of the amastigote begins after 24 h of the invasion of the trypomastigote form. The binary division starts with a gradual increase in the parasite body size, where two basal bodies arise, initiating the division of the kinetoplast and modification of nuclear chromatin, which condenses. A new flagellum begins to form. The nucleus acquires an elongated aspect, then occurring a constriction in the middle, giving rise to a cell with two nuclei and having two kinetoplasts. A cytoplasmic constriction then occurs that leads to the separation of the new forms of the parasite. The division cycle occurs every 14 h, varying according to the strain, nature of the host cell, and temperature. After a certain number of divisions (approximately 9), the amastigote forms undergo differentiation into trypomastigotes. This differentiation is known as **metacyclogenesis** and begins with the growth of the flagellum and structural change of the kinetoplast. Metacyclogenesis is synchronous, however, the molecular basis of this kinetics is not known. At the end of the intracellular cycle, a large number of extremely mobile trypomastigotes are formed. These new forms' intense movement leads to the disruption of the host cell and release of the trypomastigote forms (de Souza, 2009; Tonelli et al., 2010; Martins et al., 2012; Gonçalves et al., 2018).

Ultrastructure

T. cruzi has eukaryotic cell structures, but some specializations are found in its morphological stages and related to vital functions and success in host infection (Fig. 1).

The parasite's **cell surface** has a particular molecular association between different glycoconjugates and structural components of the plasma membrane. This association is essential in the initial interactions of parasite-host cell and host immune response (de Souza, 2009; de Souza et al., 2010a; Ferreira Cura Das Neves et al., 2020).

Below the plasma membrane of *T. cruzi* there is a helical distribution of microtubules—**subpellicular microtubules**—fundamental for the shape and locomotion of this protozoan (de Souza, 2009).

Fig. 1 Taxonomic classification and the ultrastructure of the different stages of *T. cruzi*. (A) Taxonomic classification of *T. cruzi*. (B) Giemsa-stained *T. cruzi* epimastigotes. (C) Schematic illustration of the epimastigote architecture of *T. cruzi* and organelles. (D) *T. cruzi* trypomastigote in a thin blood smear stained with Giemsa. (E) Schematic illustration of the trypomastigote architecture of *T. cruzi* and organelles. (F) Nest of *T. cruzi* amastigote in a cardiac tissue section stained with hematoxylin and eosin. (G) Schematic illustration of the amastigote architecture of *T. cruzi* and organelles. The images (B, D and F) were kindly provided by Prof. Dr. Ivan Neira Cortés.

From the flagellar pocket, the flagellum originates with variable length through the different stages of the parasite that confers locomotion and helps in the initial adhesion of the parasite to host cells.

In the cytoplasm of *T. cruzi* some structures are special and aligned to the metabolism of the parasite. In epimastigotes and amastigotes forms, near the flagellum, there is the **cytostome**, a specialized portion of the plasma membrane that invaginates through the flagellar pocket. This structure internalizes and metabolizes macromolecules for parasite survival (de Souza, 2009). Besides, the **reservosome**, a pre-lysosomal organelle, stores macromolecules from the cytostome. The reservosome is vital during the metacyclogenesis of the *T. cruzi*, especially from epimastigote to trypomastigote, when nutrients become scarce and the stored molecules are then used by the parasite (de Souza, 2009; de Souza et al., 2010a).

The **glycosomes** are organelles related to glycolytic and metabolic pathways such as peroxide metabolism, β -oxidation of fatty acids, phospholipid synthesis, carbon dioxide fixation, purine recycling, pyrimidine biosynthesis, fatty acid elongation, isogenoids, and sterol biosynthesis (de Souza, 2009). Many of these metabolism stages are potential targets for new chemotherapy and have been extensively studied.

The **acidocalcisome** is an acidic vacuolar organelle with high phosphorus concentration in the form of pyrophosphate or polyphosphate and calcium (Docampo et al., 2011). Cytochemical studies have shown the presence of H^+ ATPase, Ca^{2+} ATPase, and pyrophosphatase in the acidocalcisome membrane. The amount of these organelles varies according to the form of the parasite, with a relatively high amount in amastigotes when compared to epimastigotes and trypomastigotes (Benchimol et al., 1998). Ions such as sodium, potassium, zinc, and iron can be found in acidocalcisomes (Docampo et al., 2011). Among the functions described for this organelle are the maintenance of cytoplasmic pH, osmoregulation, storage of ions, and phosphate compounds such as pyrophosphates and polyphosphates (Docampo et al., 2005).

The **kinetoplast** is a unique structure composed of circular extranuclear DNA whose rings are concatenated in maxicircles and minicircles, known as **kinetoplast DNA (kDNA)** (de Souza, 2003; Cavalcanti et al., 2009). The ultrastructural morphology of the kinetoplast and its location in the cytoplasm determine the morphological stage of the parasite (Riou and Yot, 1977). In epimastigote and amastigote forms, the kinetoplast presents as a compacted rod located in the posterior portion of the nucleus and anterior to the flagellum, while in trypomastigotes, kinetoplast has a rounded shape with less compacted DNA and is located in the anterior portion of both the flagellum and nucleus (Riou and Yot, 1977). The kDNA cycle is similar to the bacterial system replication, which leads to the use of antibiotics as a therapeutic option against parasite infection.

Recently, multivesicular structures, called **exosomes**, were reported in *T. cruzi*. These membrane-based vesicles contain proteins, enzymes, RNAs, nucleic acid, and other molecules, and are secreted from the surface of the parasite. **Exosomes** are present in several eukaryotic cells, but in the case of *T. cruzi* may be related to signal transmission between parasites and induction of inflammatory responses in the infected host (Colombo et al., 2014; Lovo-Martins et al., 2018; de Souza and Barrias, 2020).

Biological diversity of *Trypanosoma cruzi*

Genome organization

T. cruzi presents a complex genome, where aneuploidies in hybrid strains and repetitive clusters of different gene families were found. This genomic variety may result from the degree of adaptation of the protozoan to different environments within the two hosts in its life cycle.

Size, ploidy, and chromosomes

The complete genome of *T. cruzi* is predicted to be around 105 Mb in length, distributed across 20 to 46 chromosomes (Henriksson et al., 1996; Lewis et al., 2009; Souza et al., 2011; Reis-Cunha et al., 2018). A difference of up to 47.5% (equivalent to ~73 Mb of DNA) is found in the genome size of different strains, which is attributed to both nuclear and kinetoplast DNAs (Dvorak and Howe, 1976; Castro et al., 1981; Lanar et al., 1981; Dvorak et al., 1982; McDaniel and Dvorak, 1993; Lewis et al., 2009). The amplitude found in the number of chromosomes is due to the frequency of aneuploidies (gain or loss of chromosomal copies) between and within strains, despite being predominantly a diploid organism. This fact may be associated with the degree of genome plasticity regarding parasite fitness (Reis-Cunha et al., 2018).

T. cruzi's genome is organized in small homologous pairs of chromosomes that present a significant variance in number and size among the strains (Henriksson et al., 1996, 2002; Brisse et al., 2003; Pedroso et al., 2003; Branche et al., 2006). This variance may probably be due to the location of surface molecule genes in subtelomeric regions that suffered rearrangements for immune modulation and evasion overtime (Souza et al., 2011). Moreover, up to 50% difference in certain genetically equivalent chromosomes and size differences reaching up to 1.9 Mb in some strains suggest that larger chromosome rearrangements and fusions occurred through the evolutionary process (Gaunt et al., 2003; Heitman, 2006; Messenger and Miles, 2015). Interestingly, during cell division (mitosis), *T. cruzi* chromosomes poorly condense precluding classical cytogenetic analysis (Santos et al., 1997).

T. cruzi has been considered a clonal organism that replicates by binary fission (asexual process) (Tibayrenc et al., 1990; Tibayrenc and Ayala, 2002). Recently, recombination events were found to be frequent in *T. cruzi* populations (Ramírez et al., 2012; Baptista et al., 2014; Ramírez and Llewellyn, 2014; Messenger et al., 2015b; Tomasini and Diosque, 2015). Independent exchange of DNA content in the nucleus and kinetoplast has been reported in natural populations (Messenger and Miles, 2015), indicating that hybridization has contributed to the present parasite population structures and the evolution of distinct *T. cruzi* subgroups.

Trypanosoma cruzi genome

The *T. cruzi* genome contains ~12,000 genes (CL Brener strain) with a minimum of ~10,800 for Sylvio strain (Franzén et al., 2011) and up to a maximum of ~15,300 for Dm28c (Berná et al., 2018). Approximately 50% of the genome is repetitive and presented as tandem arrays or pseudogene copies (El-Sayed et al., 2005). Recently, these repetitive genes were divided into well-conserved core genes presenting a lower GC content (48%) and variable genes, mainly coding for the multigenic surface families with a higher GC content (53%) (Berná et al., 2018).

Repetitive DNA

The most representative multigene families (e.g., TS, MASP, Mucins, DGF-1, and gp63) are related to host-pathogen interaction at the cellular level (adhesion, invasion, infection) and in immune modulation responses and thus to the success and pathogenicity of infection in the vertebrate host (Reis-Cunha et al., 2015).

The *trans*-sialidase (TS) superfamily comprises proteins that can be secreted or anchored to the surface membrane via glycosyl-phosphatidylinositol (GPI). TS is encoded by 1430 genes that are found usually near telomeric regions and, for this reason, are related to the expansion and size variability in the genome due to the exposure to the immune system pressure (Hansson et al., 2005). TS family proteins present four main functions: (i) the transfer of the sialic acid from host's cell glycoconjugates (sialylation) to parasite's β -galactosidase (β -Gal) mucins via *trans*-sialidase enzyme, which negatively charges the trypomastigote's membrane therefore protecting from the attack of anti- α -galactosyl antibodies (Pereira-Chioccola et al., 2000; Buschiazzi et al., 2002); (ii) binding and stabilization of the contact between the host cell receptors and the parasite, which determines the tissue tropism as by the conserved motif FLY domain, present in 371 members of this family, which shows tropism to heart, esophagus, and bladder endothelium (Magdesian et al., 2001a; El-Sayed et al., 2005; Tonelli et al., 2010); (iii) act as parasite-derived neurotrophic factor, together with tyrosine kinase receptors, TS proteins work as an antiapoptotic factor in mammalian cells, facilitating the persistence of the parasite in infected tissues (Chuenkova and Pereira, 2000; de Melo-Jorge and PereiraPerrin, 2007); (iv) complement regulatory proteins (CRPs) that restricts the activation of the complement pathway and therefore the lysis of the parasite (Norris et al., 1991).

Mucins (TcMUCs) are the most commonly expressed glycoproteins on the surface of *T. cruzi* ($\sim 2 \times 10^6$ copies/parasite) during different life stages. Mucins are the third most widely expanded gene family with approximately 863 genes (being 201 pseudogenes). TcMUCs have two main functions: to protect the parasite from both the vector and the host immune mechanisms and to ensure the anchorage point and invasion of specific cells and tissues (Buscaglia et al., 2006).

The MASP-encoding is the most recently discovered gene family in the *T. cruzi* genome and comprises 1377 genes and 433 pseudogenes distributed in arrays of up to 600 kb (Arner et al., 2007). It is named mucin associated surface protein (MASP) due to their proximity to mucin genes. MASP family is characterized by conserved *N*-terminal signal peptide, a conserved *C*-terminal domain containing a GPI anchor addition site, and a variable central region (De Pablos and Osuna, 2012). The distribution of the genes for these proteins among those for other surface proteins may help maintain genetic diversity (Bartholomeu et al., 2009). Also, a role in the immune evasion during the acute phase of Chagas Disease was proposed for this gene family (Villalta et al., 2001).

Dispersed gene family 1 (DGF-1) contains 565 genes and 136 pseudogenes (El-Sayed et al., 2005), which are located in subtelomeric chromosome regions where the variability in their sequences may be favored (Kim et al., 2005; Kawashita et al., 2009). The DGF-1 family members stimulate genetic diversity by gene duplication, recombination, or hybridization (Kawashita et al., 2009). They are present with greater abundance in amastigotes than in trypomastigotes and epimastigotes. The variation in those protein location during parasite differentiation and the high amount of members found in different parasite life stages (Lander et al., 2010) reveals the importance of the DGF-1 family in the biology of *T. cruzi* (Ulrich et al., 2011).

Gp63 family is GPI anchored metalloproteases that are found widely expanded in *T. cruzi* (400–700 genes or pseudogenes) (El-Sayed et al., 2005). More than 60% of those genes are assigned as pseudogenes and, although the function of this family is not elucidated yet in *T. cruzi*, in *Leishmania* they seem to have a role in invasion and innate immune evasion (Weinkauff and Pereiraperrin, 2009; Weinkauff et al., 2011). Transcriptomic analysis showed that most of those proteins are highly expressed in trypomastigotes while few expressed exclusively in amastigotes. Phylogenetic analysis of the 3'UTR region of gp63 family members revealed three distinct groups: one with genes highly expressed in trypomastigotes, another one with genes highly expressed in amastigotes, and the third group of genes with almost no expression in any stage of the parasite (Tonelli et al., 2010).

In addition to the multicopy gene families, retrotransposons and satellite DNA (tandem repeat sequences) also contribute to the repetitive nature of the *T. cruzi* genome. Retrotransposons (or class I transposable elements) are repeated DNA sequences with the ability to move from one to another *locus* in the genome by reverse transcription of an intermediate RNA into DNA upon insertion (Thomas et al., 2010). These elements were related to the parasite evolution by reshaping genomes through genetic rearrangements as creating, disrupting, shuffling genes, and even modulating the expression pattern (Thomas et al., 2010). Tandem repeats are classified according to their monomer or cluster length in micro (monomers size from 2 to 5 bp), mini (from 15 to 100 bp), and macro-satellite or satellite (greater than 100 bp) (Charlesworth et al., 1994). Around 5–10% of the genome is composed by the 195 bp satellite (TcSAT1) (Sloof et al., 1983; El-Sayed et al., 2005), being variable among strains (differences of up to six-fold), but organized similarly throughout the genome (Hoft et al., 1989). A part of the 195 bp satellite, other several tandem repeats are composed of protein-coding genes organized in tandem where the intergenic regions are highly conserved. The broad distribution of tandem repeats along the *T. cruzi*'s genome and the antigenicity indicate that they work as a mechanism triggering a polyclonal immune response, deceiving the host immune response and allowing parasite immune evasion (Berná et al., 2018).

Single copy genes

Recently, Berná et al. (2018) found 5000 single-copy genes in Dm28c, of which only 1377 have an assigned function. Some genes, previously considered to be single-copy, form a cluster of a few copies, leading to copy number miscalculations, as the lipamide dehydrogenase gene (dos Santos et al., 2016) which exhibits seven copies in TCC strain and six in Dm28c strain. This may be why *T. cruzi* is traditionally considered a refractory organism to genetic manipulation.

kDNA

Trypanosomatids present another genome in their single mitochondria (kinetoplast DNA—kDNA), composed of ~30 copies of 20–50 kb maxicircles and thousands of copies of ~1 kb minicircles (Lukeš et al., 2002; Messenger et al., 2012). The kDNA accounts for 20% of the parasite's total DNA (Baptista et al., 2014; Messenger et al., 2015a) and comprises two types of circular DNA molecules called maxicircles (the longer and functional equivalent of eukaryotic mitochondrial DNA) and minicircles (the shorter—max 2 kb—and encoding gRNAs). gRNAs are short RNA molecules responsible for guiding RNA editing, a process of post-transcriptional modifications (the addition and deletion of uridines). Maxicircle coding regions (~63% of the *T. cruzi* maxicircle genome) are homogeneous (Messenger et al., 2012), while minicircle sequences are highly heterogeneous even within a single clone (Telleria et al., 2006).

Gene expression

Genes in trypanosomatids are organized into non-overlapping clusters on the same DNA strand with unrelated predicted functions. Genes are transcribed mostly by RNA polymerase II into long polycistronic primary transcripts composed of clusters of unrelated genes (10 to 100) that are processed through coupled *trans*-splicing (a mechanism described 30 years ago in trypanosomatids, it is the processing of polycistronic RNA to mature monocistronic mRNA through two consecutive transesterification reactions that utilize two RNA molecules, the spliced leader RNA and the pre-mRNA) and polyadenylation (the addition of a tail of several adenosines poly(A) to a messenger RNA's 3' end to mature the mRNA for translation) to obtain mature individual mRNAs (Souza et al., 2011). This fast processing of the primary transcript causes the loss of the 5' start site, making the finding of promoters in this parasite difficult. It seems that the typical RNA polymerase II promoters are not present in *T. cruzi*'s genome (Souza et al., 2011) and, therefore, it is not clear how transcription is initiated. In *T. cruzi*, gene clusters can range from ~30 to 500 kb separated by divergent or convergent strand-switch regions (SSR) (Myler et al., 1999). Epigenetic mechanisms also may regulate gene expression as histone modifications and chromatin-modifying enzymes/variants (Hanke et al., 1996; Elias et al., 2001; da Cunha et al., 2006; Respuela et al., 2008). Recently, the enrichment of histone modifications associated with transcription initiation at SSR was demonstrated in *T. cruzi* (Respuela et al., 2008). Gene expression in *T. cruzi* is mainly regulated post-transcriptionally, i.e., at the level of *trans*-splicing efficiency, mRNA stability and decay, translation efficiency, and post-translational modifications (Martínez-Calvillo et al., 2010). Additionally, gene duplication and the clustering of various genes in multi-cistronic transcription units have been suggested as common means by which trypanosomes regulate protein levels (Santos et al., 1997).

Molecular genotypes

Historically, the population structure of *T. cruzi* was characterized to define the relevant subgroups using different approaches as zymodemes (Miles et al., 1977, 1978, 1981), schizodemes (Morel et al., 1980), biotemes (Andrade and Magalhães, 1996), clonets (Tibayrenc and Ayala, 1991), lineages (Souto et al., 1996), clades (Kawashita et al., 2001), discrete typing units (DTUs) (Tibayrenc, 1998), and haplotypes (de Freitas et al., 2006; Herrera et al., 2007). First, Miles and collaborators classified the *T. cruzi* subpopulations using a biochemical tool (enzyme electrophoresis) in three zymodeme groups (Miles et al., 1977). Zymodeme 1 and 3 groups were associated with sylvatic transmission cycles and Zymodeme 2 with domestic transmission cycle. In 1999, for the first time, an expert committee revised all the current knowledge on the biological and biochemical features of *T. cruzi* strains (biotemes and zymodemes) characterized by molecular techniques and recommended the division of the parasites in two major groups: *T. cruzi* I and *T. cruzi* II (Anonymous, 1999). With the advance of the knowledge on *T. cruzi* diversity, multilocus genotyping revealed six distinct DTUs with two major subdivisions: DTU I and DTU II (Brisse et al., 2001). This first DTU classification was based predominantly on clonal evolution (Tibayrenc et al., 1986), then the report of field hybrid strains in *T. cruzi* populations (Sturm and Campbell, 2010) and also experimentally generated hybrid strains (Gaunt et al., 2003) together with the gained knowledge on *T. cruzi* evolution made necessary a new revision of the *T. cruzi*'s nomenclature. A second expert meeting occurred in 2009 to standardize the nomenclature based on the characterization of *T. cruzi* eco-epidemiological features, pathogenicity, and questions of basic biology (Zingales et al., 2009). Since then, *T. cruzi* strains are subdivided into seven discrete typing units (DTUs): TcI to TcVI and Tcbat, being associated with different geographic distribution and transmission cycles (Miles et al., 2009; Zingales et al., 2009, 2012; Pinto et al., 2012; Lima et al., 2015). The term discrete typing unit is defined as “sets of stocks that are genetically more similar to each other than to any other stock and that are identifiable by common genetic, molecular or immunological markers” (Tibayrenc, 1998). In Table 1, a summary containing *T. cruzi*'s genotype classifications (actual and former) and epidemiological features is displayed.

Different evolutionary models have been proposed to explain the origin of *T. cruzi* hybrid lineages: the “Two Hybridization” (Westenberger et al., 2005), the “Three Ancestor” (de Freitas et al., 2006), the “*Trans*-sialidase” (Burgos et al., 2013) and most recently the “Hybridization and Mitochondrial Introgression” (Tomasini and Diosque, 2015) models (Fig. 2). Even though these

Table 1 Summary of former genotype classification, geographic distribution, vector, transmission cycle, host, and disease associations of *T. cruzi*'s DTUs.

DTU genotype	Abbreviation	Former <i>T. cruzi</i> genotype	Geographic distribution	Vectors	Transmission cycle	Chagas Disease pathophysiology	Sylvatic hosts
<i>T. cruzi</i> I	TcI	<i>T. cruzi</i> I and DTU I	Latin America and North America (South): more frequent in the North of the Amazon and sporadic in the Southern Cone	Primary: <i>Rhodnius</i> spp. Secondary: <i>Panstrongylus</i> spp. <i>Triatoma</i> spp. <i>Eratyrus</i> spp.	Domestic and Sylvatic	Cardiomyopathy	<i>Didelphis</i> , rodents, primates, <i>Tamandua</i>
<i>T. cruzi</i> II	TcII	<i>T. cruzi</i> II and DTU IIb	Southern Cone (mainly Atlantic and Central Brazil), sporadic further North	Not completely known (Triatominae)	Domestic (rarely in Sylvatic)	Cardiomyopathy, megasyndromes	Atlantic forest primates, <i>Didelphis</i> , <i>Euphractus</i> (Paraguay)
<i>T. cruzi</i> III	TcIII	Z3/Z1 ASAT, Z3-A, DTU IIc and <i>T. cruzi</i> III	South America	<i>Panstrongylus geniculatus</i>	Sylvatic (rare in humans and dogs)	Acute cases in Amazonian Brazil. Clinical presentation poorly known	Armadillos (especially <i>Dasyus</i> , <i>Chaetophractus</i> , <i>Euphractus</i>); <i>Didephids</i> , <i>Monodelphis</i>
<i>T. cruzi</i> IV	TcIV	Z3, Z3-B and DTU IIa	North America (South) and South America (North)	<i>Rhodnius</i> spp., <i>Panstrongylus</i> spp., <i>Triatoma</i> spp.	Predominantly sylvatic with hotspots of domestic transmission in Venezuela and North of Brazil	Secondary cause of CD in Venezuela, sporadic elsewhere in South America	Primates, <i>Nasua nasua</i>
<i>T. cruzi</i> V	TcV	Bolivian Z2, rDNA 1/2, clonet 39 and DTU IIId	Southern Cone (greater Gran Chaco and Extreme South of Brazil)	Not completely known	Domestic (rare in Sylvatic)	Cardiomyopathy, megasyndromes	<i>Dasyus</i> , <i>Euphractus</i> , <i>Octodon</i>
<i>T. cruzi</i> VI	TcVI	Paraguayan Z2, Zymodeme B and DTU IIe	Southern Cone (greater Gran Chaco and Extreme South of Brazil)	Not completely known	Domestic (rare in Sylvatic)	Cardiomyopathy, megasyndromes	Not completely known
<i>T. cruzi</i> bat	Tcbat	Not applicable	Central and South America	Not known	Not known (one human case reported in Colombia)	Apparently asymptomatic (TcBat is able to invade mammalian cells but don't cause tissue damage)	Bats (mainly insectivorous, frugivorous and nectarivorous)

models disagree about the ancestral strains and the number of hybridization events during *T. cruzi* evolution, they all agree that TcV and TcVI are hybrids, originated from parental TcII and TcIII strains. It is still unknown if these hybrids arose from a single hybridization (Messenger et al., 2012) or multiple independent recombination events (Virreira et al., 2003; Piron et al., 2007; Tomasini and Diosque, 2015). Molecular data suggest that these two hybrid lineages evolved recently, reinforcing the assumption that genetic exchange could still drive the emergence of *T. cruzi* recombinant isolates (Virreira et al., 2003; Messenger et al., 2012).

Among the DTUs, TcI is the lineage that shows the highest genetic heterogeneity, possibly due to its dispersion throughout the Americas, which is compatible with a long-term evolution. In the sylvatic cycle, TcI infects about 50 mammalian genera and a significant number of triatominae genera turning the sylvatic TcI populations extremely diverse (Llewellyn et al., 2009). In contrast, human infection with TcI is prevalent in the north of South America, Central America, and Mexico, thus presenting a considerable reduction in genetic diversity. Genetically, five intra-DTU TcI genotypes (Ia, Ib, Ic, Id, Ie) were described based on sequence polymorphisms in the mini-exon intergenic region (Fallá et al., 2009; Cura et al., 2010).

From the six DTUs, TcI, TcII, TcV, and TcVI are usually involved with the domestic cycle of Chagas disease, accounting for most human infections (Zingales et al., 2012). Human infections caused by TcI strains are more prevalent from Central America to Bolivia, while TcII, TcV, and TcVI human infections are more common in the Southern cone of South America, encompassing countries like Argentina, Chile, Paraguay, Bolivia and Brazil (Barnabé et al., 2011; Zingales et al., 2012; Fernández et al., 2014; Lima

Fig. 2 *T. cruzi* evolutionary models.

et al., 2014). Recently, several TcVI parasites were isolated from humans and vectors in Colombia, suggesting that the distribution of this DTU could be broader than previously speculated (Messenger et al., 2016).

kDNA clades

Three mitochondrial clades were identified by *T. cruzi* maxicircles phylogenetic analyses: clade A comprising TcI maxicircles; clade B comprising TcIII, TcIV, TcV, and TcVI maxicircles; and clade C comprising TcII maxicircles (de Freitas et al., 2006; Messenger et al., 2012). Although maxicircle sequences are usually conserved within a DTU, evidence of intra-lineage mitochondrial introgression (when the maxicircle genome from a DTU is associated with a non-recombinant nuclear genome of a different DTU) was found (Machado and Ayala, 2001; de Freitas et al., 2006; Carranza et al., 2009; Messenger et al., 2012; Messenger and Miles, 2015). Besides introgression, the occurrence of minor heteroplasmy (the presence of heterogeneous mitochondrial genomes in an individual cell) has also been reported (Messenger et al., 2012; Messenger and Miles, 2015). The mechanism and the role of both processes in *T. cruzi* evolution are still unclear, however, they may be important to avoid the accumulation of deleterious mutations resulting from clonal reproduction (Ramírez and Llewellyn, 2014; Messenger and Miles, 2015).

Life cycle of *Trypanosoma cruzi*

Cycle in the vertebrate and invertebrate hosts

T. cruzi is a heteroxenic protozoan which presents distinct stages of development in invertebrate and vertebrate hosts. Throughout its life cycle in the different hosts, *T. cruzi* endures several microenvironmental factors such as pH and temperature changes, nutrient availability, and osmotic and oxidative stress that threatens its survival (Wheeler et al., 2013; Melo et al., 2020). To ensure complete its life cycle successfully and colonize a host efficiently, the parasite uses different strategies by undergoing complex changes in morphology, metabolism, and gene expression profile (Jimenez, 2014).

The life cycle scheme of *T. cruzi* is displayed in Fig. 3. During a blood meal, the infected triatominae insect eliminates metacyclic trypomastigotes along with its urine/feces on the host's skin (López-Vélez et al., 2019). These parasite forms enter into the host through the bite wound, injured skin, or mucosal surface. Triatominae insect excreta induce a cytokine storm, including tumor necrosis factor alpha (TNF- α) and chemokines ligand-2 (CXCL2) and -ligand 3 (CXCL3) at the inoculation site followed by

Fig. 3 Life cycle of *Trypanosoma cruzi* in triatomine insect and mammalian host. Note: After feeding on blood containing trypomastigotes (A), the parasites migrate to the vector midgut, where they differentiate into spheromastigotes—intermediate form—(B) and epimastigotes in the anterior midgut (AM). In the posterior midgut (PM) epimastigotes multiply and adhere to the perimicrovillar membranes of the intestinal cells (C). In the rectum (RT) the epimastigotes multiply intensely, attach to the rectal wall and turn into infectious metacyclic trypomastigotes that are eliminated in vector's feces and/or urine (D). In the following blood meal, the triatomine releases the infective metacyclic trypomastigotes, which penetrate the mammalian host (human, opossums, armadillos, raccoons, among others) by scratching/rubbing or through injured skin near to the bite site. Trypomastigotes invade cells and are internalized inside the parasitophorous vacuole (0–4 h) from which they escape, and differentiate into the dividing amastigote (12–24 h) that multiplies freely in the cytoplasm by binary fission (24–72 h) (E). After about 9 cycles, these intracellular forms differentiate back into trypomastigotes (72–120 h). Alternatively, amastigotes prematurely released from infected cells, or derived from the extracellular differentiation of trypomastigotes, may also invade cells and continue an infective cycle (F). After the cell disruption, the bloodstream forms can reach a variety of tissues through blood/lymphatic circulation or be taken by the insect vector (G). The most well-characterized parasite reservoirs are represented in the box named *T. cruzi* tissue tropism. Microscopic images were kindly provided by Prof. Dr. Ivan Neira Cortés. *Epimastigotes and amastigotes are the replicative forms found in the insect midgut and mammalian cells, respectively. Meanwhile, the metacyclic trypomastigote (in the insect vector) and the bloodstream trypomastigote (in the vertebrate host) are the non-proliferative and infectious stages of the parasite.

recruitment of neutrophils and monocytes. This strong inflammatory reaction induces edema favoring the escape of metacyclic trypomastigotes into lymph/blood vessels (López-Monteón et al., 2019). The establishment of the infection depends on the parasite's ability to invade and differentiate into a replicative stage inside mammalian host cells (Lidani et al., 2017; Melo et al., 2020). The parasite invasion leads to the formation of an endocytic vacuole (called parasitophorous vacuole) which subsequently merges with a lysosome – an endocytic pathway present in all eukaryotic cells. Apparently, the trypomastigote stimulates, by exposing itself to a low pH from the lysosomal enzymes, the secretion of lytic enzymes that pierces the vacuolar membrane and enables the parasite to be adapted to the cytoplasmic environment. Then, the parasite is differentiated in the form of intracellular amastigote (De Souza et al., 2010b; Horta et al., 2020). The amastigotes multiply asexually (by binary fission), forming pseudocysts in many host tissues mainly in cardiac, smooth, and skeletal muscles and reticuloendothelial cells in the liver, and spleen. Inside pseudocysts, after many cycles of multiplication, amastigotes differentiate into trypomastigotes and are released into the extracellular environment, either infecting adjacent cells to initiate new replicative cycles or reaching the bloodstream and lymph to spread to other tissues (Lidani et al., 2017; Melo et al., 2020).

Triatomine insects feeding on an infected host may ingest trypomastigotes circulating in the blood, which pass to the midgut where they differentiate into spheromastigotes, an intermediate form. The differentiation of spheromastigotes into epimastigotes is a response to decreasing glucose levels as the blood meal is digested (Tyler and Engman, 2001). The epimastigotes multiply by longitudinal binary fission in the hindgut and migrate to the rectum, where they attach to the intestinal cuticle by their flagella and differentiate into infectious metacyclic trypomastigotes, thereby completing the parasite life cycle (Fig. 3).

Transmission forms

Although the vectorial transmission has been controlled or interrupted in many countries after governmental efforts, *T. cruzi* is still mainly transmitted in endemic areas by contact with feces/urine of infected blood-sucking triatominae insects (subfamily Triatominae) (de Lana and de Menezes Machado, 2017). They usually bite an unprotected skin area as the face (hence its common name 'kissing bug') and during blood feeding, the insect excretes parasites that enter the body through scratching at the bite area (WHO, 2020). Around 140 species of Triatominae insects widely distributed in the Americas are known to transmit *T. cruzi* (Schofield and Galvão, 2009; López-Monteón et al., 2019).

T. cruzi can also be transmitted orally by consumption of contaminated food/drinks; by blood transfusion or organ transplantation from infected donors; and congenitally (from an infected mother to her newborn); as well as by laboratory accidents (Liu and Zhou, 2015). More recently, these transmission routes have gained attention, especially in developed countries, in which up to 25% of immigrants may be infected with *T. cruzi* (Schmunis, 2007). The oral transmission has also raised attention in the last decades, due to recurring outbreaks of parasite-contaminated food and drink products consumption, usually associated with severe symptoms and high fatality rates (Shikanai-Yasuda and Carvalho, 2012; Cielo et al., 2017).

Mechanisms of infection

Adhesion of *Trypanosoma cruzi* to vertebrate cells

In the vertebrate host, the first invasion stages require adhesion of metacyclic trypomastigote's flagellum to the cell's membrane. The subsequent adhesion of parasites to vertebrate cells depends on the interaction of surface molecules between host cells and parasites, acting as receptors-ligands. The variety of these molecules involved in adhesion demonstrates the tropism and versatility of the type of tissue that can be invaded by the parasite (Pech-Canul et al., 2017). The amount and type of surface molecules vary according to the strain and morphological stage of the parasite and the type of host cell. Either way, adhesion triggers cascades of different signals that stimulate various cellular events. Despite the breadth of adhesion molecules involved, signaling will trigger the same secondary messengers and transcription factors to ensure invasion (De Souza et al., 2010b) (Fig. 4A).

The metacyclic trypomastigote presents a varied number of glycoconjugates (glycoproteins and glycolipids) on its surface, forming a layer called the glycocalyx. Among those glycoconjugates, mucins and glycoinositolphospholipids (GILPs) are the most frequent (Romano et al., 2012).

To support the process of attachment and invasion of host cells, these glycoconjugates and other groups of molecules seem to be important in modulating the immune response of the host (Pech-Canul et al., 2017). For example, the gp85/*trans*-sialidase family contains members of Tc85, gp82, gp35/50, *trans*-sialidases, among other surface glycoproteins. Tc85 molecules can bind to different receptors on the cell surface or extracellular matrix, such as cytokeratin, laminin, and fibronectin (Giordano et al., 1999; Tonelli et al., 2010). While gp82 mediates tyrosine phosphorylation and initiates phospholipase C and IP3 in host cells, resulting in calcium mobilization necessary for parasite invasion (Ramirez et al., 1993; Ruiz et al., 1998; Magdesian et al., 2001b). While gp82, which triggers a dicalcium signaling, is present in most virulent strains such as the G strain, gp35/50 that poorly induces calcium release is more concentrated in less virulent strains such as CL Brenner. *Trans*-sialidases transfer sialic acid from the host cell to the glycoconjugates of the parasite, which provide resistance to the human complement system (Zingales et al., 1987; Tomlinson et al., 1994). Another important group of molecules is proteases, such as oligopeptidase B, a soluble peptidase that indirectly induces the release of calcium during invasion (Burleigh and Andrews, 1995) and Tc80 that hydrolyzes fibronectin and collagen type I and IV present in the extracellular matrix to facilitate the penetration process (Santana et al., 1997; Grellier et al., 2001). In addition, other molecules present on the surface of the parasite, such as gp83 and penetrin, also act as ligands to extracellular matrix elements that promote cell adhesion and penetration (Ortega-Barria and Pereira, 1991; Villalta et al., 1992). The recognition and adhesion phases trigger different signaling pathways, resulting in a dependent and independent lysosome invasion processes and vary according to the type of host cell.

Cell invasion

The invasion process dependent on the presence of lysosomes occurs in non-phagocytic cells (such as epithelial and fibroblast cells) and phagocytic cells (Romano et al., 2012) (Fig. 4A). During the recognition phase, signaling cascades of cyclic adenosine monophosphates (cyclic AMPs) are triggered, inducing a bidirectional increase in calcium concentration in both parasite and host cell cytoplasm. This calcium promotes the reorganization of the cell microtubules causing the migration of lysosomes to the invasion site and the depolymerization of actin filaments at the site of parasite adhesion to facilitate invasion (Low et al., 1992; Rodriguez et al., 1995, 1999; Woolsey and Burleigh, 2004). The fusion of lysosomes with the plasma membrane is a natural mechanism of mammalian cells to repair the damaged membrane. The release of the lysosomal sphingomyelinase induces deformation of the membrane, while lysosomal membranes partially reconstitute the plasma membrane of the host cell (Reddy et al., 2001; Andrews, 2002). Additionally, it was shown that the parasite takes advantage of this membrane repair mechanism to invade the cells (Fernandes et al., 2011).

The invasion processes independent of lysosomes also occur, resulting in endocytosis in nonphagocytic cells and phagocytosis in professional phagocytic cells (De Souza et al., 2010b) (Fig. 4A). In these cases, the parasite recognition triggers kinase proteins such as tyrosine kinase and phosphatidylinositol (PI)-3-kinase in phagocytes or cyclic AMPs and PI-3-kinase in a nonprofessional

phagocytic cell, leading to the accumulation of PI-(3,4,5)-triphosphate in the host cell membrane. The high concentration of PI-(3,4,5)-triphosphate in the cell membrane causes a reorganization of the actin filaments. This reorganization induces the formation of pseudopods (in the case of phagocytosis) or invagination of the cell's plasma membrane (endocytosis) to internalize the parasite (Burleigh and Woolsey, 2002; Burleigh, 2005).

All invasion mechanisms (lysosome mediated invasion, endocytosis, and phagocytosis) culminate in an intracellular endocytic vacuole or parasitophorous vacuole where the parasite will stay obligatory and temporarily (Fig. 4A). This vacuole membrane is composed mainly of the host cell membrane and endoplasmic reticulum (ER) membrane, but the parasite can also modulate its composition. Besides, the parasitophorous vacuole membrane contains β -1 integrin (Hall et al., 1991), glycoconjugates (Barbosa et al., 1992), early endosome markers (EEA1—early endosome antigen 1, Rab 5) (Wilkowsky et al., 2002), secondary endosome protein (Rab 7) (Wilkowsky et al., 2002), autophagic protein (LC3) (Romano et al., 2009), and lysosomal membrane proteins (LAMP1 and LAMP 2) (Wilkowsky et al., 2002). These molecules indicate that the vacuole containing the parasite belongs to the traditional endocytic pathways when intracellular digestion of endocytosed material occurs through lysosomal enzymes. These events suggest that the parasite utilizes the same mechanisms as mammalian cells use for membrane repair to invade and subvert the host cell microbicidal defense to establish the intracellular infection. Moreover, the high capacity of skeletal muscles and cardiomyocytes to repair their damaged membranes could explain the tropism of *T. cruzi* for these cells (Fernandes and Andrews, 2012).

Escape of the parasite to the cytoplasm

Shortly after internalization, the vacuoles containing parasites fuse with lysosomes as they do in the endocytic pathway. However, unlike other intracellular pathogens that prevent lysosome fusion, this event is crucial for establishing *T. cruzi* infection (Andrade and Andrews, 2004). After fusion, lysosomes release enzymes that acidify the intravacuolar environment to digest the parasite, but the parasite uses this low pH to secrete its activated enzymes that help it to escape to the host cytoplasm (Andrews and Whitlow, 1989; Andrews et al., 1990). The combined action of *trans*-sialidase and neuraminidase removes sialic acid from the parasitophorous vacuole membrane, making it more vulnerable. Then, the enzymes Tc-Tox and perforin cause the rupture of pores in the vacuole membrane, which facilitates the outflow of parasites to the host cytoplasm (Andrews and Whitlow, 1989; de Carvalho and De Souza, 1989) (Fig. 4B).

Parasite multiplication and evasion of the host cell

Approximately 24 h after invasion, the parasite reaches the cytoplasmic environment and differentiates into amastigote form due to the low pH (Tomlinson et al., 1995) to initiate its intracellular replicative cycle and establish the infection (Fig. 4C). After approximately 5–6 days of cell infection and many multiplication cycles, the movements of trypomastigotes in the cytoplasm burst the host cell membrane, releasing the trypomastigotes in the extracellular environment from where they can infect new adjacent cells or reach the bloodstream (Osorio et al., 2012) (Fig. 4D).

Fig. 4 Metacyclic trypomastigote during the processes of invasion and establishment of intracellular infection. (A) The recognition of surface molecules found in parasite and host cells leads to attachment and triggers signaling pathways to allow parasite invasion. The invasion is mediated by three different processes depending on the cell type, including lysosome or phosphatidylinositol-(3,4,5)-triphosphate accumulation in the plasma membrane of the host cell or the reorganization of actin filaments. All internalization events culminate in an endocytic or parasitophorous vacuole, containing parasite that will fuse with lysosomes to degrade the internalized parasite through lysosomal enzymes. (B) However, the low pH activates parasite enzymes that disturb and rupture the vacuole membrane, allowing the parasite to escape to the host cytoplasm. (C) In the cytoplasm, the metacyclic trypomastigote differentiates into amastigote, the replicative form. (D) After several cycles of multiplication, the amastigotes evolve to trypomastigotes and rupture the cell, infecting new adjacent cells or reaching the bloodstream.

Mechanisms of immune evasion

The long interaction of *T. cruzi* with vertebrate hosts has provided this protozoan a sophisticated mechanism to evade the host immune system (Aufderheide et al., 2004; Lidani et al., 2017). Although both innate and adaptive immune responses are induced against *T. cruzi* infection, this response is not totally effective in the clearance of the parasite, driving the infection towards the chronic phase (Ramírez-Tolosa and Ferreira, 2017; Acevedo et al., 2018).

Trypanosoma cruzi resistance to the complement system

An essential immune evasion strategy used by *T. cruzi* seconds after the infection resides in its capacity to inhibit or disrupt different steps of the activation of complement (the first line immune response in the vertebrate host), avoiding opsonization, immune stimulation, and its lytic effects (Lidani et al., 2017). The complement system is a crucial component of innate immunity comprising more than 50 circulating proteins and cell surface receptors/regulators, which acts in the host defense against infections and recognition and removal of damaged or self-altered components (Ricklin et al., 2010; Andrade et al., 2017). In fact, *T. cruzi* holds a range of molecules that interfere, particularly, in the assembly/decay of C3/C5 convertases and thereby inhibits important complement-mediated processes, such as opsonization, phagocytosis, generation of anaphylatoxins C3a and C5a and lysis, among others. Following, the main *T. cruzi* factors that interfere in complement activation will be covered in more detail.

T. cruzi calreticulin (TcCRT): is a multifunctional ER protein that is translocated to parasite surface, where it mediates infection (Ferreira et al., 2004; González et al., 2015). TcCRT can bind to different pattern recognition molecules, such as C1q, MBL, and ficolin-2, thereby interfering at the initial stage of classical and lectin pathways (Table 2) (Ferreira et al., 2004; Sosoniuk et al., 2014). In addition, C1q on the parasite surface may facilitate *T. cruzi* internalization into mammalian cells contributing to the survival strategy of *T. cruzi* (Rimoldi et al., 1988; Malhotra, 1993).

Trypomastigote decay acceleration factor (T-DAF): is a glycoprotein analogous to human DAF, a membrane protein that prevents complement activation on autologous cells. T-DAF is expressed in the surface of *T. cruzi* trypomastigotes (metacyclic and tissue-culture-derived) but not epimastigotes (Kipnis et al., 1986, 1988; Tambourgi et al., 1993). T-DAF acts as a negative complement regulator (Tambourgi et al., 1993), favoring *T. cruzi* survival in the host.

T. cruzi complement C2 receptor inhibitor trispanning (TcCRIT): a protein expressed by distinct parasite strains that acts as a receptor for C2 inhibiting its cleavage by C1s (Inal and Schifferli, 2002). TcCRIT is expressed in metacyclic trypomastigotes, but not in epimastigotes (Cestari et al., 2008, 2009) and its overexpression in transgenic parasites confers high resistance against complement-mediated lysis (Cestari et al., 2009), contributing to *T. cruzi* survival enabling the infection to progress (Table 2) (Cestari et al., 2008, 2009).

T. cruzi complement regulatory protein (TcCRP): also known as gp160, is a surface-anchored glycoprotein that presents genetic and functional similarities to human DAF (Norris et al., 1991). It is expressed in trypomastigotes (metacyclic and tissue-culture-derived), but not in epimastigotes or intracellular amastigotes (Norris et al., 1989, 1991). TcCRP has the ability to inhibit the assembly of classical and alternative C3 convertase, enabling *T. cruzi* to evade the lytic effect of complement (Table 2) (Norris et al., 1991; Norris and Schimpf, 1994; Norris, 1998). TcCRP expression varies among *T. cruzi* strains, with most virulent strains having higher TcCRP expression levels (Henrique et al., 2016).

T. cruzi complement regulatory gp58/68 (gp58/68): this protein prevents the interaction of factor B with parasite-bound C3b to form the C3 convertase (Table 2) (Fischer et al., 1988). By this means, *T. cruzi* gp58/68 favors evasion from the alternative pathway supporting parasite survival.

In addition to the surface regulatory molecules, *T. cruzi* releases microvesicles during infection as another strategy to circumvent the effect of complement (Ming et al., 1995; Cestari et al., 2012; Ramirez et al., 2017). During *T. cruzi* infection both parasite and host cells may release microvesicles (Cestari et al., 2012; Torrecilhas et al., 2012; Ramirez et al., 2017) that can confer protection against complement attack and enhance *T. cruzi* cell invasion (Cestari et al., 2012; Torrecilhas et al., 2012) (Table 2). Moreover, monocytes and lymphocytes-derived microvesicles may carry TGF- β (Ming et al., 1995) and thereby enhance *T. cruzi* cell invasion (Cestari et al., 2012). In addition, microvesicles released by *T. cruzi* may carry important virulence factors that affect the parasite--host interaction promoting infection (Torrecilhas et al., 2012; Garcia-Silva et al., 2014b, a; Fernandez-Calero et al., 2015).

Trypanosoma cruzi evasion from phagolysosome oxidative response

Macrophages at the site of infection are among the first host cells to be invaded by *T. cruzi*, and to establish an infection, metacyclic trypomastigotes must endure the highly oxidative conditions generated inside the phagolysosome (David Sibley, 2011). The parasite relies on a sophisticated system of antioxidant proteins that acts synergistically to inactivate the macrophage oxidative process, which includes antioxidant enzymes and iron superoxide dismutase (TcSOD) (Table 2) (Wilkinson et al., 2000, 2002a, b; Piacenza et al., 2008, 2013; Mateo et al., 2008). The antioxidant metabolic network used by *T. cruzi* provides resistance against macrophage killing and consequently increases its virulence.

Table 2 *T. cruzi* molecules involved in the immune evasion mechanisms.

Parasite molecule	Expression site	Developmental stage of protein synthesis ^a	Evasion mechanisms	Reference
<i>T. cruzi</i> calreticulin (TcCRT) [also termed TcCalr, Tc45]	Parasite surface	Trypomastigotes (metacyclic)	Binds to MBL and Ficolin-2 collagen-like domain inhibiting the lectin pathway; Binds to C1q collagen-like domain inhibiting the classical pathway	Rimoldi et al., 1988; Malhotra, 1993; Sosoniuk et al., 2014
Trypomastigote decay acceleration factor (T-DAF)	Parasite surface	Trypomastigotes (metacyclic, tissue-culture-derived)	Interferes with factor B binding to C3b on the parasite surface and C4b2a formation inhibiting C3 convertase of both classical and alternative pathways of complement	Kipnis et al., 1988; Rimoldi et al., 1988; Tambourgi et al., 1993
<i>T. cruzi</i> complement C2 receptor inhibitor (TcCRIT)	Parasite surface	Trypomastigotes (metacyclic)	Binds to C2 preventing its cleavage by C1s and MASP-2, avoiding C3 convertase formation and blocking classical and lectin complement pathways	Cestari et al., 2008, 2009
<i>T. cruzi</i> complement regulatory protein (TcCRP) [also termed gp160, CRP-160, CRP-10]	Parasite surface	Trypomastigotes (metacyclic, tissue-culture-derived)	Binds to C3b and C4b inhibiting the classical and alternative C3 convertase formation	Norris et al., 1991; Norris and Schrimpf, 1994; Norris, 1998
<i>T. cruzi</i> complement regulatory gp58/68 (gp58/68)	Parasite surface or released	Trypomastigotes (metacyclic)	Interacts with factor B preventing its binding to parasite-bound C3b inhibiting the formation of C3 convertase of the alternative pathway of complement	Fischer et al., 1988
<i>T. cruzi</i> -induced membrane-derived vesicles from host cells (microvesicles)	Release during parasite infection	Trypomastigote, (metacyclic, tissue-culture-derived) and epimastigote	Binds to the C3 convertase of the <i>classical</i> and <i>lectin</i> pathways (C4b2a) on the parasite surface, inhibiting C3 cleavage	Cestari et al., 2012; Torrecilhas et al., 2012; Ramirez et al., 2017
<i>T. cruzi</i> cytosolic trypanodioxin peroxidase (TcCPX)	Parasite cytosol	Trypomastigotes (metacyclic)	Inactivates peroxynitrites, hydrogen peroxide and short chain organic hydroperoxides in phagolysosome	Wilkinson et al., 2000
<i>T. cruzi</i> mitochondrial trypanodioxin peroxidase (TcMPX)	Parasite mitochondria	Trypomastigotes (metacyclic)	Inactivates peroxynitrites, hydrogen peroxide and short chain organic hydroperoxides in phagolysosome	Piacenza et al., 2008
Glutathione peroxidases I (TcGPXI)	Parasite glycosome	Trypomastigotes (metacyclic)	Inactivates hydroperoxides in phagolysosome	Wilkinson et al., 2002a; Wilkinson et al., 2002b
Glutathione peroxidases II (TcGPXII)	Endoplasmic reticulum	Trypomastigotes (metacyclic)	Inactivates lipid hydroperoxides in phagolysosome	Wilkinson et al., 2002a; Wilkinson et al., 2002b
Ascorbate-dependent heme peroxidase (TcAPX)	endoplasmic reticulum	Trypomastigotes (metacyclic)	Inactivates hydrogen peroxide in phagolysosome	Wilkinson et al., 2002a; Wilkinson et al., 2002b; Piacenza et al., 2008
<i>T. cruzi</i> superoxide dismutase A (TcSODA)	Parasite mitochondria	Trypomastigotes (metacyclic)	Inactivates peroxynitrites and superoxide anion on phagolysosome	Mateo et al., 2008; Piacenza et al., 2013
<i>T. cruzi</i> superoxide dismutase B1 (TcSODB1)	Parasite cytosol	Trypomastigotes (metacyclic)	Inactivates peroxynitrites and superoxide anion on phagolysosome	Mateo et al., 2008; Piacenza et al., 2013
<i>T. cruzi</i> superoxide dismutase B1-2 (TcSODB1-2)	Parasite glycosome	Trypomastigotes (metacyclic)	Inactivates peroxynitrites and superoxide anion on phagolysosome	Mateo et al., 2008; Piacenza et al., 2013
<i>T. cruzi</i> superoxide dismutase C (TcSODC)	Parasite mitochondria	Trypomastigotes (metacyclic)	Inactivates peroxynitrites and superoxide anion in phagolysosome	Mateo et al., 2008; Piacenza et al., 2013
Glycoinositolphospholipids (GIPLs)	Parasite surface	Most abundant in epimastigote and metacyclic trypomastigotes	Immunomodulatory role in host cell response, including inhibition of proinflammatory cytokines and costimulatory immune molecules expression in human DCs and macrophage as well as inhibition of T cells activation	Gomes et al., 1996; De Lederkremer and Bertello, 2001; Brodsky et al., 2002; Previato et al., 2004

Table 2 (Continued)

Parasite molecule	Expression site	Developmental stage of protein synthesis	Evasion mechanisms	Reference
<i>T. cruzi</i> trans-sialidase (TcTS) [GPI-anchored mucins]	Parasite surface and released	Primarily expressed on metacyclic trypomastigote	Transfers sialic acid from host glycoconjugates to <i>T. cruzi</i> surface masking the parasite; Mediates immunomodulation of DCs response; Induces the production of non-neutralizing antibodies by B-cells and non-specific polyclonal B cells activation; Immunosuppressive role by inducing T cells apoptosis and reducing the magnitude of CD8+ T cells response due to immunodominant epitopes	Leguizamón et al., 1999; Buschiazzi et al., 2002; Gao et al., 2002; Pitcovsky et al., 2002; Martin et al., 2006; Erdmann et al., 2009
AgC10 [GPI-anchored mucins]	Parasite surface and released	Metacyclic trypomastigotes, epimastigotes and amastigotes	Immunosuppressive role by inhibiting T cells activation and IL-2 secretion	Alcaide and Fresno, 2004
Mucin-associated surface proteins (MASP) [GPI-anchored mucins]	Parasite surface and released	Primarily expressed on metacyclic trypomastigote	Immunomodulatory role on B cells by inducing the production of spurious and non-neutralizing antibodies	Bartholomeu et al., 2009; dos Santos et al., 2012
<i>T. cruzi</i> glutamate dehydrogenase (TcGDH)	Parasite cytosol	Epimastigotes	Induces B cells mitogenesis irrespective of their specificity	Montes et al., 2006
<i>T. cruzi</i> polyclonal activator of 45 kDa (TcPA45)	Cytoplasmic and membrane-associated protein	Metacyclic trypomastigote and epimastigotes	Induces B cells mitogenesis irrespective of their specificity	Reina-San-Martín et al., 2000
Heat shock protein 70 (HSP70)	Cell membrane, cytoplasmic and kinetoplast	Metacyclic trypomastigotes cultured at 29 °C	Immunosuppressive role by inducing T cells apoptosis	Marañón et al., 2000
Cruzipain (Cz)	Lysosome and parasite surface	Epimastigotes and amastigotes	Immunosuppressive role by reducing the macrophage trypanocide activity	Cazzulo et al., 1997; Stempin et al., 2002

^aEvolutive form associated to the described evasion mechanisms.

Trypanosoma cruzi immunomodulates host cell response

During *T. cruzi* infection, several immunomodulatory molecules are released and expressed by the parasite which interfere in the host responses mediated by dendritic cells (DCs), B and T lymphocytes (B and T cells), allowing parasite survival and spreading in the host (Buscaglia et al., 2006; Rodrigues et al., 2009; DosReis, 2011; Gravina et al., 2013; Acevedo et al., 2018; Ross and Cantrell, 2018).

Some virulence molecules, such as the glycoinositolphospholipids (GIPLs), and Glycosylphosphatidylinositol-anchored mucins (GPI-mucins) which, among others mechanisms inhibit DC maturation, induce the secretion of immunosuppressive cytokines and prevent the expression of proinflammatory molecules, inducing host tolerance to *T. cruzi* (Table 2) (De Lederkremer and Bertello, 2001; Buschiazzi et al., 2002; Previato et al., 2004; Poncini et al., 2008; Erdmann et al., 2009; DosReis, 2011). Factors secreted by the parasite may also play an immunosuppressive role by altering the maturation of human DCs, impairing antigen presentation and host capacity to fight *T. cruzi* infection (Van Overtvelt et al., 1999, 2002; Chaussabel et al., 2003; Poncini et al., 2008). However, these secreted *T. cruzi* factors are still not known.

Other factors belonging to the highly polymorphic multigenic protein family, such as GPI-mucins [*trans*-sialidases (TcTS) and mucin-associated surface proteins (MASPs)] (Table 2) inhibit effective adaptive immunity response by disturbing B cells activities (Pitcovsky et al., 2002; Buscaglia et al., 2006; Bartholomeu et al., 2009; dos Santos et al., 2012). Among other mechanisms, the simultaneous expression broad range of antigenic motifs delays the activation of specific B cells, driving the immune system into a series of spurious and non-neutralizing antibody responses, delaying the production of high-affinity anti-*T. cruzi* antibodies (Pitcovsky et al., 2002; Buscaglia et al., 2006; Bermejo et al., 2011).

Moreover, *T. cruzi* acute infection was associated with the subversion of signals required for T cells activation, such as IL-2 secretion, resulting in anergic T response (Gomes et al., 1996; Alcaide and Fresno, 2004; Ross and Cantrell, 2018). Anergy to T cells response allows parasite replication and spread, contributing to the establishment of chronic infection. It was also proposed that

T. cruzi may induce T cells apoptosis, affecting memory processing, and generation of specific T cells to combat the intruder in the long term infection (Leguizamón et al., 1999; Marañón et al., 2000).

In order to survive in the host and establish a life-long chronic infection, *T. cruzi* can benefit from a phenomenon known as immunodominance (DosReis, 2011; Acevedo et al., 2018). In this context, pathogen-specific T cells appear to preferentially recognize a small number of *T. cruzi* epitopes, preventing efficient pathogen elimination (Rodrigues et al., 2009). Immunodominant antigens can be selected by several factors, including stable MHC-peptide complexes on antigen-presenting cells, the affinity of T-cell receptors, as well as the abundance of parasite epitopes (Yewdell and Bennink, 1999; Goto et al., 2008; Rodrigues et al., 2009). Parasite *trans*-sialidases are among the significant known immunodominant targets for CD8⁺ T cells (Table 2), (Martin et al., 2006). Taken together, *T. cruzi* immunodominant epitopes may impair immunity to a range of other epitopes, reducing the potential of an effective response and eventually favoring parasite persistence in the chronic stage (Martin et al., 2006; Tzelepis et al., 2008; Rodrigues et al., 2009).

Trypanosoma cruzi immune evasion and latency in adipose tissue

Another escape mechanism used by *T. cruzi* to avoid the host immune defense allowing its continued persistence consists in the establishment of latency sites. In this regard, studies have shown that the adipose tissue may be an important target for *T. cruzi* during acute infection and a reservoir in the chronic phase (Combs et al., 2005; Ferreira et al., 2011; Nagajyothi et al., 2012; Morrot et al., 2016). Studies have also demonstrated that *T. cruzi* may induce deep changes in the adipocyte homeostasis, affecting the plasma levels of adipokines (Combs et al., 2005) and allowing the establishment of an inflammatory phenotype, which possibly affects parasite control contributing to disease evolution (Manarin et al., 2013; Morrot et al., 2016; González et al., 2019). The reason why *T. cruzi* persists in the adipose tissue is not completely understood, but it is possibly related to the metabolic conditions that the parasites find inside the adipocyte as well as the extremely slow turnover of these cells (Combs et al., 2005; Nagajyothi et al., 2012). Thus, adipose tissue may be a long-term reservoir for *T. cruzi* where the parasite might persist in a dormant state avoiding host defense, and from which recrudescence may occur, causing disease decades later.

Trypanosoma cruzi and disease

T. cruzi is the causative agent of CD, also known as American trypanosomiasis, that presents itself in acute and chronic phases. CD is characterized by a sophisticated and immune-driven interaction of host and parasite factors, which results in multiple clinical forms of the disease. In this context, the host-parasite relationship is key to understanding the pathophysiology of *T. cruzi* infection and its clinical progression.

Acute and chronic CD phases

The acute phase starts after the contact with *T. cruzi* and is characterized by extensive parasite replication, making parasites easily found in the bloodstream. In this phase, nonspecific symptoms, such as headaches, somnolence, pallor, fever, enlarged lymph glands, muscle pain, difficulty in breathing, swelling, and abdominal or chest pain can be observed (Prata, 2001; Lidani et al., 2019). First visible characteristic clinical signs can be observed in around 50% of the people and consist of either a skin lesion (chagoma) or a purplish swelling of unilateral eyelids (Romaña sign) resulting from *T. cruzi* inoculation (WHO, 2020). Severe CD, including myocarditis, pericardial effusion, and/or meningoencephalitis in acute phase is rare and associated with high mortality risk (Acquatella et al., 2018). Moreover, orally transmitted *T. cruzi* infection has been reported to cause more severe acute morbidity and higher mortality than vector-borne infection, possibly due to alterations in parasite surface glycoproteins caused by exposure to gastric acid which leads to increased parasite infectivity (Covarrubias et al., 2007; Yoshida, 2008).

After the acute phase (4 to 8 weeks after infection), the parasitemia decreases markedly in 90% of the cases and the infection may remain clinically silent for years or throughout life in a chronic asymptomatic (or indeterminate) form (Nunes et al., 2013). The parasite tropism for different tissues varies according to host and parasite factors, but frequently includes heart, stomach, small intestine, gut mesenteric, adipose tissue, and central nervous system (Lewis et al., 2018; Pereira et al., 2019). Over a period of years to decades, around 20 to 30% of patients will present some cardiac disorders and up to 10% will develop digestive (typically enlargement of the esophagus or colon), neurological or mixed alterations (Bern, 2015).

People with asymptomatic form present reactive serology and/or positive parasitological tests for *T. cruzi* but no evidence of organ dysfunction (mainly cardiac or digestive). The evaluation consists of nonspecific signals or symptoms related to CD; and negative tests to detect early organ damage, such as electrocardiogram, echocardiogram, chest X-ray, esophagography and barium enema (Lidani et al., 2019). Even without any evidence of abnormalities, a silent progressive process might be taking place due to the presence of *T. cruzi* in the blood or infected tissues where replication occurs (Sánchez-Valdéz et al., 2018; Alvar et al., 2020). Most infected individuals, about 60–70%, can remain asymptomatic for their entire lives.

During the infection process, the parasites can induce damage directly and by microvascular immune alterations response that leads to an imbalance in the host favoring the disease establishment (Marin-Neto et al., 2007). Consequently, an extensive infiltration of immune cells and the production of proinflammatory cytokines takes place (Bonney and Engman, 2015; Lidani et al., 2017), leading to chronic inflammation and organ damage as seen in patients with symptomatic CD forms. In this scenario,

inflammatory and fibrotic events can overlap, resulting in the cardiac form, which ranges from asymptomatic electrocardiogram abnormalities to congestive heart failure, arrhythmias, and/or thromboembolic events (Biolo et al., 2010). The typical dilated cardiomyopathy observed in most patients with heart failure related to CD consists of chronic diffuse myocarditis with tissue substitution by fibrosis, causing different types and grades of cardiac block and progressive dysfunction (Atié and Steinberg, n.d.; Marin-Neto et al., 2007). CD has also been associated with sudden death due to cardiac arrhythmias or heart failure caused by the selective destruction of the heart muscle and its neurons (Rassi et al., 2001; Dyer, 2018).

In the gastrointestinal tract, chronic infection affects mainly the lower esophageal sphincter and colon, but also salivary glands, stomach, small intestine, gallbladder, and biliary tree (Matsuda et al., 1995). The chronic injuries of the enteric nervous system lead to long-term waves, hypercontraction of muscle fibers, resulting ultimately in hypomotility of the digestive system and dilatation of the organs (Matsuda et al., 1995; De Oliveira et al., 2008; Pinazo et al., 2010). Whereas esophageal manifestations range from asymptomatic motility disorders through mild achalasia to megaesophagus; colonic involvement results in prolonged constipation, fecaloma, volvulus, bowel ischemia, or megacolon (Bern et al., 2020). The concomitant manifestation of digestive syndromes with cardiomyopathy characterizes the cardiodigestive form.

The exact molecular mechanisms underlying the pathogeny of the chronic forms of CD are still unknown. So far, critical elements related to the host genetic factors influencing the development of different clinical forms, as well as parasite polymorphism (DTUs) and tissue-tropism have been described (Villarreal et al., 2004; Nogueira-Paiva et al., 2015). It is conceivable that all these factors could influence the different outcomes of CD. The finding of specific molecular biomarkers for early cardiac and digestive damage that could be useful in defining prognosis would be a significant advance in the clinical management of CD patients.

Laboratory diagnosis

Diagnostic methods for *T. cruzi* encompass parasitological, serological, and molecular approaches. Parasitological methods aim to visualize the presence of fresh-blood parasites by microscopic examination, and their sensitivity varies according to the stage of infection and parasitemia grade (Becerril, 2011). The serological methods search for anti-*T. cruzi* antibodies in patient's serum using parasite antigens in distinct immunoassays (Guhl and Vallejo, 2003). The molecular approach consists in the detection of parasite DNA by PCR-based techniques. Although molecular methods could increment the diagnostic, its implementation in endemic regions remains limited, due to the complexity, lack of standardization, and high cost (Picado et al., 2018). It is also important to note that careful anamnesis considering the patient's history may help to identify possible risks for *T. cruzi* infection.

The main methods of determining *T. cruzi* infection according to the phases or clinical forms of CD are shown in Table 3. In the acute phase, IgM is usually positive and circulating trypomastigotes may be visualized in blood or detected by PCR techniques. In the chronic stage, due to the low parasitemia, conventional parasitological methods such as blood culture and xenodiagnosis are of low sensitivity, being serologic tests more suitable. The standard approach for diagnosing CD recommended by the WHO (WHO, 2002) requires at least two different techniques using distinct antigens, and when the results diverges, then a third assay is needed.

Table 3 Laboratorial diagnostic tests for the detection of *T. cruzi* according to the phase and clinical form of CD.

CD phase	CD form	Clinical characteristics	Laboratorial Diagnosis of infection			
			Blood smear ⁺⁺	Serology		PCR-based
				IgM	IgG	
Acute ⁺	NA	Usually mild, nonspecific symptoms	✓	✓	–	✓
Acute congenital infection ^a	NA	Asymptomatic or mild, nonspecific symptoms	✓	–	✓	✓
Early chronic	Indeterminate	Asymptomatic; ECG usually shows no abnormalities suggestive of CCC	–	✓	✓	✓
Chronic ^b	Indeterminate	Asymptomatic; ECG shows no abnormalities suggestive of CCC	–	✓	✓	✓
	CCC	ECG abnormalities suggestive of CCC, arrhythmias, syncope, left-ventricular dysfunction, heart failure	–	✓	✓	✓
	Digestive	Dysfunction followed by dilatation of esophagus, colon, or both	–	✓	✓	✓
	Cardiodigestive	ECG abnormalities suggestive of CCC, arrhythmias, syncope, left-ventricular dysfunction, heart failure. Dysfunction followed by dilatation of esophagus, colon, or both	–	✓	✓	✓

Note: The sensitivity and specificity of these tests are variable. CCC, chronic Chagas cardiomyopathy; ECG, electrocardiogram; PCR, polymerase chain reaction; IgM, Immunoglobulin M; IgG, Immunoglobulin G.

+ Positive IgM test should be recommended in cases of CD symptoms related to suggestive epidemiological history.

++ Microscopy of blood smear or buffy coat films stained with Giemsa or other appropriate stains.

^aPositive IgG serologic test for 9 months old of age or later.

^bIn cases of suspected central nervous system involvement, cerebral spinal fluid (CSF) specimens could be evaluated.

Modified from Bern C (2015) Chagas' disease. *New England Journal of Medicine* 373: 456–466. <https://doi.org/10.1056/NEJMra1410150>.

The available tests vary considerably in their performances due to the source of antigens employed, genetic diversity of the parasite, host immune responses, and disease prevalence (Umezawa et al., 1999; Leeftang et al., 2013; Balouz et al., 2017; Zingales, 2018; Díaz et al., 2019). Among the available serological tests are enzyme immunoassay (EIA) or enzyme-linked immunosorbent assay (ELISA) (Afonso et al., 2012) recombinant *T. cruzi* antigens; immunoblot (TESA) (Umezawa et al., 1996; Furuchó et al., 2008); indirect immunofluorescence (IFI) (López-Monteón et al., 2019); and indirect hemagglutination (IHA) (López-Monteón et al., 2019). Although serology is generally more appropriate in the chronic CD, a molecular test may be useful in immunosuppressed patients with re-activation of CD. Moreover, not so commonly used, heart or gastrointestinal tissue biopsy can show amastigotes (López-Monteón et al., 2019).

Molecular diagnosis is indicated in cases of suspected acute infection (including transfusion or transplant transmission), congenital CD, and for monitoring accidental laboratory exposures. The molecular detection of *T. cruzi* DNA targets mainly the kinetoplast genome (kDNA), a nuclear mini-satellite (SatDNA) region designated TCZ (Piron et al., 2007; Duffy et al., 2009; Schijman et al., 2011; Cura et al., 2017), and a small ribosomal RNA subunit (18S rRNA) (Schijman et al., 2011). Due to the high genetic variability of *T. cruzi* strains (DTUs) a multi-target PCR test is essential for more accurate results.

Treatment

Benznidazole (N-benzyl-2-nitroimidazole-1-acetamide) and nifurtimox (5-nitrofurantoin derivative) are the only options for effective treatment of *T. cruzi* infection. Benznidazole is a prodrug metabolized by parasite enzymes to become active; metabolites seem to act through several mechanisms to block *T. cruzi* glutathione and trypanothione pathways (Müller Kratz et al., 2018). Nifurtimox impedes *T. cruzi* carbohydrate metabolism through the inhibition of pyruvic acid synthesis (Forsyth et al., 2016; Bern et al., 2020). Both antiparasitic drugs must be administered at the onset of the acute phase, including congenital transmission and reactivation due to immunosuppression. During early chronic phase, in adults, regardless symptoms, some guidelines recommend antiparasitic treatment in order to prevent or cure disease progression and in pregnant women (Dias et al., 2016).

Benznidazole is the first-choice drug in most Latin American countries due to the high toxicity of nifurtimox. Even so, treatment has a suspension rate of around 20% due to poorly tolerated side effects (Jackson et al., 2010; Pinazo et al., 2013). Unfortunately, less than 10% of CD patients in the Americas have been diagnosed and only around 1% of them have access to antiparasitic treatment (DNDI, 2018). Importantly, the potential benefits of medication should be weighed against the duration of treatment (up to 2 months), contraindications (such as pregnant women), and possible adverse reactions which occurs in up to 40% of adult patients (Bern et al., 2007; Torrico et al., 2018). Thus, these drugs have been effective mainly during early infection and their benefits in the chronic CD phase remain questionable.

Important concerns associated with the use of benznidazole and nifurtimox need to be addressed such as the severe collateral effects that lead to treatment interruption; *T. cruzi* resistance to the drugs; effectiveness in the chronic phase; and specific formulations for children and pregnant women are still an emerging need (Menezes et al., 2011; Morillo et al., 2015; Ribeiro et al., 2020). In this context, development of new drugs against *T. cruzi* targeting novel mechanisms of action in order to minimize toxicity and adverse effects have been carried out by several research groups (Bernatchez et al., 2020; Ribeiro et al., 2020). Additionally, specific supportive therapy for cardiac, digestive or neurological manifestations may be required.

Acknowledgments

The authors thank Prof. Dr. Ivan Neira Cortés from the Departamento de Tecnología Médica of Universidad de Antofagasta, Chile, who kindly provided *Trypanosoma cruzi* micrographs used in Figs. 1 and 2.

Introduction

Arthropods constitute the animal phylum including the largest number of species on earth (Zhang, 2011), with at least 40,000 species feeding on/in mammals and birds (Balashov, 2006; Di Giovanni et al., 2020). They are of primary importance in medical and veterinary entomology, playing both a direct and indirect role in several of the most widespread human, pet and livestock diseases. Most of the arthropods affecting humans are bloodsucking insects, which are responsible for the transmission of some of the deadliest human and animal pathogens, both in tropical and temperate areas (Benelli and Duggan, 2018) (Fig. 1). Among arachnids, the subclass Acarina is the most important, including hundreds of species of mites and ticks, which act as dangerous pests and/or are vectors of pathogens. More than 700,000 deaths yearly are caused by pathogens transmitted by arthropod vectors (WHO, 2020). Vector-borne diseases (VBDs) include some of the most important human diseases, like malaria, dengue, African trypanosomiasis, onchocerciasis, leishmaniasis, Chagas disease, typhus, plague, tularaemia, Lyme disease, and babesiosis, just to cite some examples (Raoult and Roux, 1999; Becker et al., 2010; Brun et al., 2010; Taylor et al., 2010; Bhatt et al., 2013; Cucunubá et al., 2016; Musso and Gubler, 2016; Petersen et al., 2016; Benelli and Beier, 2017; de Fuentes-Vicente et al., 2018; Kennedy, 2019; WHO, 2019, 2020). Crustaceans are usually less important as human parasites, while they can act as intermediate or paratenic hosts of other parasites, including those that cause widespread diseases such as dracunculosis, diphyllorhynchiasis, sparganosis, and paragomiasis (Cairncross et al., 2002; Hayunga, 2013; Keiser and Utzinger, 2005; Scholz et al., 2009).

Arthropod-borne diseases played a crucial role in shaping human history. Acting as vectors of the bacterium *Yersinia pestis*, the human flea (*Pulex irritans* Linnaeus, 1758) and the human body louse (*Pediculus humanus humanus* Linnaeus, 1758) might have been the cause behind the spreading of recurrent epidemics of plague in Europe, including the Black Death (1346–1353) (Ayyadurai et al., 2010; Dean et al., 2018) (Fig. 1). Louse-borne infectious diseases, such as epidemic typhus, might have been a major factor in the Napoleon's Grand Army retreat from Russia in 1812 (Raoult et al., 2006). Mosquito-borne diseases, such as malaria and yellow fever, mined the construction of the Panama Canal by French companies, causing thousands of deaths amongst workers, costing millions of dollars and eventually forcing French to cease the project in 1889 (Lechuga and Castro, 2017); United States purchased building rights from French and were able to complete the Canal only thanks to a massive vector eradication program (Sutter, 2007).

In many developing countries, VBDs have a significant impact on health, economy and society, preventing the achievement of a sustainable development (Ehrenberg and Ault, 2005; Stolk et al., 2016). Affecting mostly children, VBDs also become a crucial factor in determining a reduction in schooling (Alonso and Alvar, 2010; Hofstra and van Brakel, 2016). Several of them may also cause severe disabilities (like blindness because of onchocerciasis, an infectious disease caused by the filarial nematode *Onchocerca volvulus* Bickel, 1982 transmitted by blackflies) or deformities (like elephantiasis caused by lymphatic filariasis agents transmitted by mosquitoes), which eventually led to social stigmatization of affected people (Molyneux, 2013; Wilke et al., 2020a). In addition, increased transcontinental mobility of men and goods, rapid urbanization and global climate changes led to the range expansion of many vectors and their related pathogens (Wilke et al., 2020b), and to the emergence or re-emergence of several VBDs also in temperate and urbanized areas in which they had never been recorded before, or from areas where they have been eradicated since long time (Barker and Reisen, 2019; Barmak et al., 2016; Becker et al., 2012; Caminade et al., 2018; Colwell et al., 2011; Dantas-Torres, 2015; Massaro et al., 2019; Wilke et al., 2019).

Arthropod parasites of humans

Only relatively few species of arthropods have evolved as specific human parasites, i.e., their development is strictly dependent on humans to complete. Follicle mites belonging to the family Demodicidae and the human lice (Phthiraptera) are ones of the few parasites specific to humans. Among Demodicidae, *Demodex folliculorum* (Simon, 1842) and *Demodex brevis* Akbulatova, 1963 are the only species that live on humans. The two species closely resemble one another but occupy different ecological niches. The first,

Fig. 1 (A) Female of the head louse, *Pediculus humanus* Linnaeus, 1758 var. *capitis*, a parasite strictly associated with humans. (B) *Ixodes* sp. tick, intent on sucking blood. Ticks are responsible of the transmission of several diseases such as tick-borne encephalitis, Crimean-Congo hemorrhagic fever, Lyme borreliosis, tularaemia, ehrlichiosis, relapsing fever, spotted fevers, Q fever, and babesiosis. (C) The sandfly *Phlebotomus papatasi* (Scopoli, 1786), responsible for the spread of visceral and cutaneous leishmaniasis. (D) Female of the Asian tiger mosquito, *Aedes albopictus* (Skuse, 1894), a potential vector of chikungunya, dengue and Zika among other arboviruses; this highly invasive mosquito species has spread to many countries worldwide through international trading routes. (A) Photo credit D. Juranek, CDC 1979, (B) photo credit L. Lenzini, (C) photo credit F. Collins, CDC 2006, and (D) photo credit L. Barraco.

D. folliculorum, occurs primarily in hair follicles, while the second, *D. brevis*, lives in sebaceous glands. Both species can infest the same host, feeding on host cells by piercing them with their styletiform chelicerae to suck cell contents (Mullen and O'Connor, 2019). They usually cause no major health problems, but their presence has been associated with minor skin issues, like rosacea, seborrheic dermatitis, and blepharitis (Sędzikowska et al., 2018; Wesolowska et al., 2014). Another skin mite that commonly infests humans is the itch mite, *Sarcoptes scabiei* (Linnaeus, 1758) (Sarcoptidae). This species is represented by a complex of physiological varieties, each with different biochemical and ecological characteristics and associated with different mammals, even if monospecificity of these host-specific varieties is still debated (Andriantsoanirina et al., 2015; Mullen and O'Connor, 2019). Sarcoptic mange constitute a significant problem for livestock in many countries (Currier et al., 2011), while the worldwide prevalence of the human-adapted variety has been estimated in more than 100 million cases in 2010 (Hay et al., 2014). *S. scabiei* var. *hominis* usually produces intense pruritus, dermatitis or allergic reactions in humans, due to the mites burrowing into hair follicles and the adult females digging burrows in the lower stratum corneum of the skin. In chronic infestations, the number of mites tends to decrease thanks to the host immune responsiveness. However, in immunosuppressed subjects, mites can multiply causing a crusted scabies (also called Norwegian scabies) and increasing risk for secondary bacterial infections (Hengge et al., 2006; McCarthy et al., 2004; Orion et al., 2006). Despite scabies mite varieties show some degree of host preference, cases have been reported of humans temporary infested with varieties associated with other animals; such infestations typically result in localized papules and temporary itchy rashes, which self-limit within few weeks, as the mite does not burrow nor survive to reproduce (Andriantsoanirina et al., 2015; Arlian et al., 1984; Mullen and O'Connor, 2019).

As for skin mites, human lice, *Pediculus humanus humanus* Linnaeus, 1758, *Pediculus humanus capitis* De Geer, 1767, and *Phthirus pubis* (Linnaeus, 1758) are strictly associated with humans. Different species are specialized on different parts of the human body.

Lice are obliged permanent ectoparasites and transmission occurs by direct contact between individuals or occasionally through contaminated clothing, bedding, and furniture (Orion et al., 2006; Ruffi and Mumcuoglu, 1981). Infestations cause symptoms like itching, erythema, papules, fever, and inflammation (Orion et al., 2006). Differently from skin mites, lice may be responsible of transmitting pathogens; *P. humanus humanus* can be vector of bacteria like *Rickettsia prowazekii* (the etiologic agent of epidemic typhus), *Bartonella quintana* (the agent of trench fever), and *Borrelia recurrentis* (a bacterium associated with relapsing fever) (Brouqui, 2011; Raoult and Roux, 1999; Schaub et al., 2012), and even a role as additional vector of plague, *Y. pestis*, from human to human has been suggested during the Black Death epidemic (Ayyadurai et al., 2010). The vector competence of *P. humanus capitis* remains controversial (Mumcuoglu, 2012; Robinson et al., 2003), whereas *P. pubis* is not known to transmit pathogens (Schaub et al., 2012).

Arthropod micropredators and vector-borne diseases

The great majority of arthropods of public health importance affecting humans are micropredators (Di Giovanni et al., 2020). Differently from parasites in a narrow sense, micropredators are free-living organisms that prey on host blood or other tissues, usually for a limited time and without forming a permanent association with their host (Di Giovanni et al., 2020; Klowden, 2019; Lafferty and Kuris, 2002; Poulin, 2011; Poulin and Randhawa, 2015). Consequently, micropredators usually show a scarce specificity, and differently from “true” parasites, they feed on multiple host individuals per generation, with hosts potentially belonging to one or more species (Di Giovanni et al., 2020; Lafferty and Kuris, 2002; Poulin, 2011). This category includes all the blood-sucking Diptera that attack humans (e.g., mosquitoes, sandflies, biting midges, blackflies, tumbu flies, tsetse flies, louse flies, stable flies), as well as insects belonging to the orders Hemiptera (kissing bugs, bed bugs, and bat bugs) and Siphonaptera (fleas), and arachnids of the subclass Acarina (mites and ticks). Blood is the typical resource of micropredators; vessel-feeders like mosquitoes, kissing bugs, bed bugs, and fleas have modified mouthparts for cannulating host dermal blood vessels (Benelli and Mehlhorn, 2018), while pool-feeders like blackflies, biting midges, horse flies, stable flies, tsetse flies, and sandflies, suck blood through micro-lacerations opened on the host skin (Lane and Crosskey, 1993). The adaptation to hematophagy combined with a general scarce host specificity, makes them perfect candidates as carriers of different pathogens, which can reproduce into the parasite body and be easily conveyed from one host to another by entering directly into the host bloodstream. A peculiar case of blood-sucking insect-mediated transmission of pathogens is represented by kissing bugs of subfamily Triatominae; kissing bugs are vector of *Trypanosoma cruzi*, the agent of Chagas disease or American trypanosomiasis (de Fuentes-Vicente et al., 2018). Instead of being passed to the host directly during the insect blood meal, the pathogen completes the development in the triatomine intestinal tract and it is excreted along with feces and urine, eventually entering the host through the wound caused by the insect bite or other lacerations of the skin (Garcia and Azambuja, 1991).

According to WHO (2020), VBDs account for about 17% of all infectious diseases and cause more than 700,000 deaths annually. Except for schistosomiasis, all the vector-borne diseases listed by WHO are transmitted by arthropods (WHO, 2020). Mosquitoes alone are responsible of transmitting some of the deadliest diseases known to man, such as malaria, yellow fever, dengue, Zika, chikungunya, yellow fever, West Nile fever and lymphatic filariasis (Becker et al., 2010; WHO, 2019, 2020). WHO estimated that 247 million people became infected from mosquito-borne diseases in 2006, with about one million people dying (Becker et al., 2010). In 2018, 228 million cases of malaria were reported and 405,000 deaths occurred worldwide; 93% of the cases were recorded in the African region and 67% of the death affected children under 5 years of age (WHO, 2019).

Some of the arthropod-borne diseases, such as dengue, chikungunya, Chagas disease, African trypanosomiasis, visceral and cutaneous leishmaniasis, lymphatic filariasis, and onchocerciasis, have been included in the WHO list of neglected tropical diseases (NTDs) (WHO, 2012), a group of tropical or subtropical diseases that affect more than one million people in the developing countries. Dengue transmitted by *Aedes* mosquitoes is considered ubiquitous throughout the tropics, with an estimate of 390 million people infected per year, 96 millions of which manifest symptoms (Bhatt et al., 2013). Chagas disease is a major public health problem in Latin America, causing nearly 22,000 deaths yearly, with about 7–8 million infected people estimated in the continent (Cucunubá et al., 2016; de Fuentes-Vicente et al., 2018). Lymphatic filariasis chiefly due to *Wuchereria bancrofti* (Cobbold, 1877) and *Brugia malayi* (Brug, 1927), accounts for 120–130 million cases, with more than 90% in African and South-East Asian regions (Mathew et al., 2020; Taylor et al., 2010), while river blindness caused by *O. volvulus* transmitted by blackflies affects nearly 37 million people in Africa and Central and South America (Taylor et al., 2010). African trypanosomiasis (sleeping sickness) occurs in 36 sub-Saharan countries, with 70 million people at risk (Kennedy, 2019). Zika outbreaks, such as the Polynesian one in 2013–2014 and the South American one in 2015–2016, were responsible for an increase in case of severe neurological complications or congenital malformations in affected countries (Musso and Gubler, 2016; Petersen et al., 2016).

Several micropredators exploit food sources other than blood. For example, mites of the family Trombiculidae primarily feed on lymph and partially digested skin cells, eventually transmitting pathogens, as for the genus *Leptotrombidium* spp. transmitting *Orientia tsutsugamushi*, the causative agent of tsutsugamushi disease (Mullen and OConnor, 2019); species of the genus *Musca* in the tropics swarm around humans and cattle to feed on suppurating sores or body secretions (Crosskey and Lane, 1993); Steganinae drosophilids of genus *Phortica* and *Amiota* feed on lachrymal secretions of animals and humans and can transmit eyeworms of the genus *Thelazia*, which cause lacrimation, ocular discharge, epiphora, conjunctivitis, keratitis, corneal opacity and ulcers (Otranto and Traversa, 2005).

Most micropredators establish a temporary relationship with their hosts, usually limited to the few seconds it takes them to complete the blood meal, but in some cases the time spent on the host can be highly variable. Several species of argasid and ixodid ticks, as well as chigoe fleas, establish a prolonged association with their host, which is no longer regarded only as a food reserve but also as a suitable environment for the development (Di Giovanni et al., 2020). In some cases, the degree of dependence between the micropredator and its host became so strict that the parasite may spend all his life on a single individual host and even require direct contact for transmission to occur efficiently. For example, females of the chigoe fleas *Tunga* burrow into the skin of a single individual host where they remain for the rest of their life. Argasid ticks are a particular group of parasitic arthropods, which evolved different parasitic strategies in terms of time spent on their hosts and time spent actually feeding on their hosts. In general, some species may be considered short-term micropredators (e.g., *Argas cucumerinus* Neumann, 1901), whereas others are long-term micropredators (e.g., *Argas transversus* Banks, 1902, *Otobius* spp., and *Ornithodoros lahorensis* Neumann, 1908). It is also worth mentioning that some larva and nymphs of argasid ticks can moult to the next stage without feeding, whereas adults of some species (e.g., *Antricola* spp. and *Otobius* spp.) do not feed at all.

Arthropods include also species of medical importance as potential mechanical vectors of human diseases. Adults of some of the most common species of calyptate flies are synanthropic, and because of their habit of feeding on human food as well as rubbish and excrement can be involved in the mechanical transmission of pathogenic organisms (Crosskey and Lane, 1993; Gestmann et al., 2012). Pathogens can be transported through hairs and microtrichia of the fly and contaminate food or can be transmitted by the fly to a substrate through defecation or partial regurgitation of the food during a meal (Crosskey and Lane, 1993). More than 100 different pathogens have been isolated from the common house fly *Musca domestica* Linnaeus, 1758, including polio, hepatitis, cholera, tuberculosis, *Salmonella*, *Shigella*, hemolytic streptococcus, or pathogenic *Escherichia coli* (Greenberg, 1971), although they do not necessarily play a significant role in the transmission of these agents from an epidemiological perspective. Flies inhabiting human settlements can potentially convey also several species of fungi, like *Aspergillus* spp. or *Candida* spp., and even helminths (Gestmann et al., 2012; Sulaiman et al., 1988). Although the number of pathogens carried by the flies is often too small to induce infection, pathogens may easily multiply when transported on suitable substrates like food or wounds (Gestmann et al., 2012).

Endoparasites of humans

Maggots of several fly families cause subcutaneous or visceral myiasis, i.e., enter live tissues and organs of vertebrate animals, and feed on host's dead or live tissues, body fluids or ingested food for a certain period of their life (Zumpt, 1965). Myiasis-causing flies may be considered as a particular type of micropredator (Di Giovanni et al., 2020), as they are still temporary parasites and do not need a direct contact between hosts to be transmitted. However, differently from blood-sucking arthropods and other micropredators, they live and feed on the host until the development is completed, and then leave it to pupate in the external environment (Balashov, 2006). No species are restricted to humans, but a few species, like *Dermatobia hominis* (Linnaeus Jr., 1781), are a plague for humans and cause significant economic losses (Sancho, 1988; Hall and Wall, 1995). In obligatory myiasis flies, the parasite depends on the host for part of its life cycle (Francesconi and Lupi, 2012). In relation to the body part attacked by the maggot, several classifications have been proposed (Francesconi and Lupi, 2012; James, 1947; Zumpt, 1965). If the larva is localized in areas such as the eyes or neck, sporadically myiasis evolve in severe complications, such as blindness or even brain damage (Edwards et al., 1984; Kalelioğlu et al., 1989).

Other flies do not need a host to complete their development but their larvae can infect humans as well, causing ailments. Several free-living flies can cause facultative myiasis in humans and other animals, or are unable to initiate a myiasis unless the host is previously infested by other species or the host is almost dead (Francesconi and Lupi, 2012). Eggs or larvae of several dipterans can be accidentally eaten and, passing through the digestive tract unharmed by digestive enzymes may cause accidental enteric myiasis (Hall and Smith, 1993). Rarely, accidental myiasis can result from larvae that enter the rectal or urogenital tract, hatching from eggs laid in the perianal area, like in the case of myiasis caused by the cosmopolitan lesser house fly *Fannia canicularis* (Linnaeus, 1761) and the latrine fly, *Fannia scalaris* (Fabricius, 1794) (Hall and Smith, 1993; Zumpt, 1965).

Maggots of myiasis flies are one of the few endoparasitic arthropods. Another exception is represented by the enigmatic clade of tongue worms (Pentastomida), a group of bizarre crustaceans that reproduce into nasopharyngeal region of carnivores or respiratory tract of large snakes (Mendoza-Roldan et al., 2020; Tappe and Büttner, 2009). The sporadic human cases are related to larvae of two species, *Linguatula serrata* Frölich, 1789 and *Armillifer armillatus* (Wyman, 1845), that cause visceral pentastomiasis when humans accidentally ingest parasite eggs from respiratory secretions or faeces from their natural definitive hosts.

Other arthropods of medical and veterinary importance

The importance of arthropods in human parasitology is also given by the role they play as intermediate or paratenic hosts in the life cycle of other parasites. Copepods are intermediate hosts of the broad fish tapeworm *Dibothriocephalus latus* (Linnaeus, 1758) (= *Diphyllobothrium latum*), the cestod genus *Spirometra* spp., and of the nematodes *Gnathostoma spinigerum* Owen, 1836 and *Dracunculus medinensis* Linnaeus, 1758 (Cairncross et al., 2002; Hayunga, 2013; Herman and Chiodini, 2009; Scholz et al., 2009). In the marine environment, members of the parasites taxa Digenea, Cestoda, Nematoda, and Acanthocephala, are common parasites frequently including pelagic and benthic crustaceans in their life cycle (Busch et al., 2012). First larval instars of the

nematode *Anisakis* spp. and *Pseudoterranova* spp. usually infect euphausiids (“krill”), but also copepods, skeleton shrimps, and Decapoda can act as intermediate hosts (Busch et al., 2012; Kagei et al., 1978; Uspenskaja, 1960). Mites of order Oribatida are intermediate hosts of primate tapeworms of the genera *Bertiella* and *Mesocestoides*, that occasionally affect humans (Mullen and OConnor, 2019).

Several human infections can be acquired through the consumption of raw or undercooked infected crabs or crayfish, which act as intermediate hosts in the cycle of helminths. The paragonimiasis, caused by the lung fluke *Paragonimus westermani* Kerbert, 1878 (Hayunga, 2013; Yokogawa, 1969), is one of the most widespread food-borne disease due to raw crustacean consumption, interesting an estimate of 293,8 million people in Asia, Africa and America (Keiser and Utzinger, 2005; Liu et al., 2008). In some cases, crustaceans act as paratenic hosts, i.e., harbor the sexually immature stages of a parasite even if they are not necessary for the parasite to complete its cycle; this is the case of crayfish hosting the larvae of the Chinese liver fluke *Clonorchis sinensis* Loos, 1907, or the nematode *Angiostrongylus cantonensis* (Chen, 1935), which are responsible of clonorchiasis and angiostrongyliasis in humans, respectively (Dooley and Neafie, 1976; Hayunga, 2013; Wang et al., 2012).

Furthermore, the accidental ingestion of arthropods can be the cause of infestations by several parasites; the intake of non-purified water containing infected copepods is the basis of the life cycle of the guinea-worm, *D. medinensis*. Dracunculiasis is one of the most ancient known human disease, so that it is believed the “fiery serpents” of the Israelites or symbolic serpents in the Greek caduceus are actually guinea-worm representations (Biswas et al., 2013; Hayunga, 2013). In 1986, its annual incidence was estimated in 332 million people, with 120 million people at-risk (Watts, 1987), and it has been dramatically reduced thanks to eradication campaigns that have led to a reduction of cases up to 99% (Ruiz-Tiben and Hopkins, 2006). Accidental ingestion of copepods may be also the cause of infestations by *G. spinigerum* or *Spirometra* spp. (Hayunga, 2013).

More rarely, humans can be infested by parasites after accidentally swallowing insects like ants harboring *Dicrocoelium dendriticum* (Rudolphi, 1819), fleas with *Dipylidium caninum* (Linnaeus, 1758) or *Hymenolepis diminuta* (Rudolphi, 1819), and beetles and cockroaches which may carry the acanthocephalans *Moniliformis moniliformis* (Bremser, 1811) and *Macracanthorhynchus hirudinaceus* (Pallas, 1781) (Hayunga, 2013). Transmission of the apicomplexan *Hepatozoon* spp. to an intermediate vertebrate host may take place by the accidental ingestion of infected ticks (Dantas-Torres et al., 2012; Giannelli et al., 2013).

A wide range of other arthropods are of medical importance, even though they cannot be considered parasites of humans, and do not take part in the life cycles of other human parasites. These species cause direct harm to humans, because of the presence of offense/defence mechanisms, or indirectly, in attending the same places inhabited by man. Most aculeate Hymenoptera and even few parasitic wasps (i.e., Ichneumonoidea) can sting humans for self-defence, causing from a moderate and short (usually characterizing solitary species) to very intense and persistent pain (usually characterizing social species that live in colonies), occasionally leading to systemic reactions (Schmidt, 2009, 2016). The venom of several spiders and scorpions can cause transitory to systemic reactions that range from mild to life-threatening symptoms (Mullen and Sissom, 2019; Mullen and Vetter, 2019). Other arthropods are capable of remarkable and harmful defence mechanisms, as for the explosive exothermic secretions of some carabid beetles (Di Giulio et al., 2015), or produce highly toxic molecules such as pederine and cantharidin (Frank and Kanamitsu, 1987; Iserson and Walton, 2012; Moed et al., 2001). Larvae of many insects are armed with toxic setae or spines, which may cause burning sensation or urticaria on skin by contact or induce allergic reactions if ingested or inhaled (Mullen and Zaspel, 2019). Members of several families of mites can cause allergic responses in humans by direct contact of mites with the skin, inhalation of mites or mite parts, or ingestion of mite-contaminated food (Arlian, 2002; Colloff, 2009). House dust mites or mold mites (e.g., members of the families Pyroglyphidae, Acaridae, Glycyphagidae, and Carpoglyphidae), which commonly live in human dwellings, feeding on stored products or skin detritus, may be responsible for respiratory allergies and asthma (Calderón et al., 2015). Under certain conditions of exposure, mites may even enter natural body orifices, leading to cases of temporary pulmonary, enteric or urinary acariasis (Mullen and OConnor, 2019).

Conclusions and challenges for future research

Overall, arthropods and arthropod-borne diseases have a considerable impact on public health and livestock production both in tropical and temperate areas. Many of those diseases can have tremendous social and economic consequences in countries where large outbreaks occur (Gopalan and Das, 2009; Egdenbewe-Mondzozo et al., 2011; Gubler, 2012). Over the years, WHO (2012) produced evidences that the burden caused by several infectious diseases can be effectively controlled and, in several cases, eliminated or eradicated. The WHO Assembly issued several resolutions on the control of selected diseases. In 2011, a roadmap was drafted for the control, elimination and eradication of NTDs, which affect more than 1 billion people in the world; the resolution considered arthropod-borne diseases such as dengue, Chagas disease, sleeping sickness, leishmaniasis, onchocerciasis, and lymphatic filariasis, and set ambitious targets to be achieved during the period 2012–2020 (WHO, 2012). WHO recommendations include preventive mass-administration of drugs and enhanced access to care on a large scale, intensified disease management and improved case-detection, effective vector control, including the proper management of intermediate hosts or host reservoirs, veterinary public health, and access to safe water, sanitation and hygiene. These goals require a background made by an increase in health awareness and education (WHO, 2012). Despite considerable progresses, many of these diseases are far from being defeated. Global control and eradication programs achieved a clear reduction in number of infected people and in the resulting economic losses (Mathew et al., 2020). The Global Burden of Diseases, Injuries, and Risk Factors Study (GBD, 2017) estimated a reduction in percentage of all-age deaths due to malaria and NTDs by about 30% from 2007 to 2017. Unfortunately, the

application of control measures is often neglected during periods of political instability, especially in tropical areas, thus leading to resurgence (Brun et al., 2010).

In addition, during the last years, several VBDs became an emerging global scale problem, due to increasing in transcontinental migrations, international trade, rapid urbanization, deforestation and climate change (Barker and Reisen, 2019; Barmak et al., 2016; Basile et al., 2011; Becker et al., 2012; Caminade et al., 2018; Connors et al., 2016; Dantas-Torres, 2015; Martins-Melo et al., 2014; Massaro et al., 2019; Parham et al., 2015; Walsh et al., 1993). Changing environmental conditions may also enhance the possibility of arising of novel host-virus interactions, as for recent outbreak of chikungunya in Northern Italy, resulting from the contact between an infected person coming back from tropical areas and a previously introduced vector, the Asian tiger mosquito, *Aedes albopictus* (Skuse, 1894) (Becker et al., 2010; Sambri et al., 2008).

The control and eradication of arthropod vector populations is a crucial and timely challenge (Benelli and Duggan, 2018), which can be won only through a multidisciplinary approach integrating human, animal, and environmental health (Benelli et al., 2016; Benelli and Beier, 2017; Benelli and Duggan, 2018; Di Giovanni et al., 2020; Mackenzie et al., 2013). Past disease management approaches, such as the frequent and massive use of synthetic insecticides to fight vectors, can no longer be sustained. The large use of synthetic insecticides gave rise to the spread of insecticide resistance in vectors, and caused concern regarding potential negative effects on human health and environment (Hemingway et al., 2016; Benelli et al., 2016). New management programs must rely on Integrated Vector Management strategies, more respectful of the environment and people's health, such as the release of natural enemies of arthropod parasites and vectors or of sterile vectors. At the same time, a more in-depth investigation of ethological aspects and population dynamics of parasites and vectors are needed (Benelli et al., 2016; Benelli and Duggan, 2018). To enhance interdisciplinary collaborations and communications amongst all subjects involved in VBD management, new worldwide strategies, like One Health and EcoHealth, have been proposed (Benelli and Duggan, 2018; Bergquist et al., 2017; Mackenzie et al., 2013). In this scenario, the collection of entomological and ecological data, monitoring of vector populations, studies on the biology and ecology of vectors and transmitted pathogens, all require global concerted actions, that involve experts and data from multiple research fields as well as education and active community participation.

Introduction

Mosquitoes (Diptera, Nematocera: Culicidae) belong to a monophyletic group containing about 3600 species (Wilkerson et al., 2015) with cosmopolitan distribution, to which belong 44 genera and 145 sub-genera (Wood and Borkent, 1989; Miller et al., 1997; Harbach and Kitching, 1998; Harbach, 2007). It is estimated that they originated in the Jurassic period of the Mesozoic Era, between 200 and 150 million years ago (Reidenbach et al., 2009). They are distributed from the coldest areas, close to the Poles, to the tropical belts and equator, including the desert zones. They are considered absent only in Antarctica and in few islands.

Mosquitoes historically influenced human activities more than any other insect group, not only for their constant nuisance, but more importantly for their role in the transmission of pathogens to humans and animals (Ayala and Coluzzi, 2005; White et al., 2011). The pathogens transmitted by mosquitoes include viruses, protozoa, helminths (Becker et al., 2010) and possibly at least a bacterial species (*Rickettsia felis*), for which mosquito vector competence has been recently demonstrated (Laroche et al., 2018). Despite less than 5% of mosquito species are involved in disease transmission (Harbach, 2007), they are by far the most important cause of morbidity and mortality among humans than any other known animal species, particularly in tropical areas (“WHO Mosquito-borne diseases” www.who.int/neglected_diseases/vector_ecology/mosquito-borne-diseases/en). In recent years, moreover, the increasing global trade and the gradual change of climate patterns favored the spread of invasive species in several countries (Kraemer et al., 2019; Wilke et al., 2019, 2020; Benelli et al., 2020), particularly in temperate areas, posing the basis for new transmission routes of pathogens and unexpected epidemiological scenarios. Despite the huge efforts made in recent years, mosquito control is still a global public health problem far from being resolved.

Generalities on morphological characteristics

Mosquitoes measure about 0.5–1 cm with a slender structure and the typical subdivision of the insect body of in head, thorax and abdomen. As all dipterans, they have one pair of mesothoracic wings, with the second pair modified to halteres, structures that serve to stabilize the flight. A distinctive element of the family is the presence of the proboscis, a piercing-sucking mouth structure suitable to exploit blood and sugar substances of vegetable origin. The only exception is the subfamily Toxorhynchitini, a non-hematophagous group in which the proboscis is sclerotized and unable to pierce host skin, becoming a mouth apparatus specialized in nectar feeding.

The sexes are easily distinguished by the presence of distinctive phenotypic characters; the females have filiform antennae and usually short maxillary palps (except for the subfamily Anophelinae, in which the palps have the same length as the proboscis), while the males have feathery antennae, palps as long as the proboscis (the latter is not structured as a “channel” for sucking) and the external copulatory apparatus (*hypopygium*) structured with claws at the extremity of the abdomen, which serves to hold the female during the copulation. The adult body is covered by thin scales of variable color which, depending on their disposition and abundance, give typical colorations to the species and are useful for the taxonomic determination, together with other less evident characters such as the distribution of bristles and the morphology of the *hypopygium*.

The mosquito larvae are aquatic filter feeders, apod, eucephalic. One of the distinctive elements of the mosquito larvae is the dilated thorax, larger than the abdomen and the distinct head without raptatory antennae (which are instead typical of the family Chaoboridae, the taxonomically closest group). The abdomen ends with a respiratory siphon or spiracles with which mosquito larvae breathe atmospheric air at the water surface. The taxonomic features of the species in the larvae are the antennae, the bristles present on the head and body, a series of bristles and spicules on the VIII abdominal segment and the respiratory siphon, when

present (subfamily Culicinae). The shape and structure of the latter, as well as the anal segment, also have typical structures useful for identification.

Life cycle

Like all holometabolous insects, mosquitoes have a life cycle that allows larvae and adults to exploit completely different ecological niches. Following the laying of eggs (on or near the surface of the water) by a female, which are usually matured thanks to a blood meal, the aquatic and filtrator larva completes four stages of development. Then, it pupates into a mobile pupa from which, once the metamorphosis is completed, a flying adult emerges on the water surface (Fig. 1). Each time interval of the above-mentioned phases changes according to the species, with a large variability. Eggs normally need a few days to complete embryonic development. However, several adaptive strategies involve this stage, particularly in the *Aedes* genus, leading to an interruption of egg maturation until water submerge the eggs oviposited on a potential breeding site or the climatic conditions become suitable for mosquito survival. Larvae can take form a few days up to some weeks to complete their development, while pupae usually complete the metamorphosis within 1–2 days. Once emerged, adults mate as soon as possible, usually with male swarms which attract virgin females with complex behavioral mechanisms including visual markers, circadian time synchronization, flight patterns, pheromones and wingbeat frequency (Clements, 1999; Gibson and Russell, 2006; Gibson et al., 2010; Cator et al., 2009; Manoukis et al., 2009; Fawaz et al., 2014). Females mate once, usually with a single male, preserving the sperms in spermathecae for all life. After copula, the male of several species usually releases a mating plug on the female gonoduct to avoid other copulation events, thus preventing polyandric fertilization. This process alters both female physiology and behavior, inducing refractoriness of the female to mate (Degner and Harrington, 2016). At each gonotrophic cycle, eggs will be fertilized by the sperms before oviposition. Several oviposition events can occur in the female lifetime, producing at each event a variable number of eggs, ranging from few dozens to few hundreds depending on the species. Mosquitoes can survive from a few weeks up to several months, according to the species and survival strategies. Adults are often the phase of the life cycle that overcomes the adverse season (winter or dry season) through an overwintering/aestivation strategy. The diapausing adults tend to hide in sheltered microhabitats with stable climatic conditions, such as sewerage networks, natural cavities, basements, etc., and then reactivate during the favorable season. The last blood meal taken before diapause has the function of overcome hibernation phase through gonotrophic dissociation and development of energetic resources on fat bodies useful to survive during the period of inactivity (Clements, 1992).

Larval ecology

Mosquito larval development is strongly dependent from the nature of the breeding site, both in terms of trophic web and water composition. The breeding sites exploited by mosquito larvae are stagnant water collections that can be of different sizes, from small containers or crevices to lagoons or rice fields (Fig. 1; Becker et al., 2010). Many species of health interest are associated to synanthropic environments, from rural to urbanized areas, developing in small and medium water collections (e.g., *Aedes aegypti*, *Aedes albopictus*, *Culex quinquefasciatus*, *Culex pipiens* and *Culex coronator*, Soghigian et al., 2017; Wilke et al., 2020). The major urban breeding sites used by these mosquitoes are cisterns, purification tanks, roadside drain pipes, ornamental tanks and fountains, used tyres, bins and buckets used to collect rainwater in vegetable gardens, vases in cemeteries and under racking. In rural and agricultural areas, on the other hand, the main breeding sites are the network of canals and ditches used for irrigation. Finally, rice paddies represent a type of environment highly suitable to the development of other species of public health interest, such as several species

Fig. 1 Life cycle of three representative mosquito genera: (A) *Anopheles* sp., (B) *Culex* sp., (C) *Aedes* sp. The major morphological characteristics of the development phases are shown, as well as the breeding habitats typically exploited by these genera.

belonging to *Culex pipiens* complex and several *Anopheles* species (e.g., *Anopheles maculipennis* complex, *Anopheles gambiae* complex, *Anopheles freeborni*, *Anopheles albimanus*, Smith et al., 1988).

According to species, gravid mosquito females distribute the eggs of a single gonotrophic cycle in several breeding sites (scatter oviposition), as it frequently happens in container-breeding mosquitoes such as those belonging to *Aedes* genus, or they lay the whole egg batch in a single site, as it often happens in *Culex* and *Anopheles* species (Day, 2016). These two strategies are strongly dependent to how larvae are adapted to different water habitats: large stable water collections are often rich in organic matter, with a structured and complex biocenosis in which predators are abundant, while small ephemeral habitats can have lower biodiversity but also fewer nutrients. The rapidity of the larval development, as well as their behavioral strategies for nutrition intake and predator avoidance typical of each mosquito species, affect the oviposition site choice and larval phase completion. The duration of the larval development is also influenced by environmental factors, such as water temperature (higher temperatures reduce the time to complete the larval phase).

An emblematic example of these two opposite strategies is given from the afro-tropical species complex *Anopheles gambiae* sensu lato, to which belong the major malaria vectors in the world (Coluzzi et al., 1985; Toure et al., 1998; Coluzzi et al., 2002). Three of the sibling species of this complex, *Anopheles gambiae* sensu stricto, *Anopheles coluzzii* and *Anopheles arabiensis*, differentially exploit larval habitats ranging from rain-filled temporary water sources (mostly *A. gambiae* s.s. and *A. arabiensis*) up to large permanent man-made water collections (*A. coluzzii*). These species also show a different larval tolerance to salinity and pollution (Gimonneau et al., 2012; Kamdem et al., 2012; Tene Fossog et al., 2013, 2015). The ecological factors involved in the larval habitat segregation of these species are not completely known but a different ability to escape predators or tolerate abiotic stress have been identified (Lehmann and Diabate, 2008; Gimonneau et al., 2012; Roux et al., 2014).

Hematophagy and host-seeking behavior

The trophic regime of mosquitoes varies according to the sex and age of the individual: males feed throughout their lives exclusively on sugary plant substances, obtained from flowers, fruits and honeydew. The females feed on sugary liquids as well (Barredo and De Gennaro, 2020), but after mating they need blood meals to mature their eggs (Clements, 1992). Blood is a nutrient source with high protein content, and as such it can provide the large amounts of amino acids necessary for the development of eggs. The blood meal takes place at different times of the circadian clock, depending on mosquito species. Most species take a single blood meal for egg maturation of a gonotrophic cycle, while some species need multiple meals. The female can uptake from 3 to 6 μL of blood in a single meal, requiring from 1 to 3 min for its completion (Becker et al., 2010). To complete the blood meal, mosquitoes, as all hematophagous arthropods, release saliva into the host before and during the blood intake process. The biological purpose of saliva is to allow the blood intake, minimizing the time of feeding and avoiding the reaction by the host. Salivary secretions have specific biochemical properties and contain dozens of secretory proteins, whose functions are still only partially known, in particular anticoagulants, vasodilators, platelet aggregation inhibitors and immunomodulators (Ribeiro and Arcà, 2009). These proteins have the function of keeping the blood fluid during sucking and preventing the formation of clots that could occlude the mouthparts. Besides, they promote meal intake by limiting the inflammatory response that may increase the host's perception of mosquito presence. Already during the probing phase preceding blood intake, mosquitoes release their saliva superficially into the host skin to prepare the environment for subsequent perforation by the mouthparts. Mosquitoes have a piercing-sucking apparatus that during blood intake is inserted through the epidermis to reach the dermis. The perforation of the skin is done until a blood capillary is reached. At this point, the mosquito introduces into the wound all the fascicle, except for the sheath (labium), which is folded and used as a guide to facilitate the sliding of the stilets (labrum, hypopharynx, maxillae and mandibles). The sharp maxillae represent the main penetrative element, while labrum and hypopharynx delimit respectively the salivary channel (from which saliva is introduced) and alimentary channel (from which blood is taken) separated from each other by the mandibular stylets.

Mosquitoes are temporary ectoparasites that are associated with the host only for blood meal intake and in response to specific physiological signals. Long-distance localization of the host is ensured by sophisticated neurosensory systems, adapted according to biting behavior, that can occur during daytime or the night (Fig. 2). Specific receptors (thermal, olfactory, chemo- and mechanoreceptors) located on the antennae and/or the palps, facilitate the recognition of these different stimuli and orientate the mosquito towards the host, favoring the choice of the optimal site of the body where to take the blood meal (Takken, 1991; Dekker and Carde, 2011; Montell and Zwiebel, 2016). In diurnal mosquitoes (mainly *Aedes* but it has been observed also in night-biting *Anopheles coluzzii*) a combination of visual and olfactory stimuli play an important role (Kennedy, 1940; Van Breugel et al., 2015; Hawkes and Gibson, 2016). In nocturnal mosquitoes (e.g., *Anopheles* and *Culex*), which feed when the ambient temperature is low, an important stimulus can be the orientation towards heat sources, in addition to the ability to perceive water vapor, carbon dioxide produced by breathing and other volatile organic components (such as lactic acid, octenol, acetone) emanated by tetrapods through breathing and muscle activity and present in sweat and sebum. To these are added substances produced by the bacterial microflora of the skin, whose catabolites are an integral part of the complex odor blend characteristic of a specific host (Wooding et al., 2020). The long-distance identification of the host by the mosquito female is done flying upwind following a source of carbon dioxide emitted by the host (Rebollar Téllez, 2005; Takken and Verhulst, 2013). Once near the potential host, other substances that direct the mosquito to the point of biting, such as water vapor, organic compounds and body temperature, come into play (Fig. 2). Some species of mosquitoes feed on a wide variety of hosts, while others feed exclusively on certain species (Lehane, 2005; McBride et al., 2014). Differences in host preference exist not only among different species but also among populations of the same mosquito species and

Fig. 2 Schematic diagram describing the different stimuli followed by a diurnal mosquito (e.g., *Aedes* sp.), on the left, and a nocturnal mosquito (e.g., *Culex* sp.), on the right.

even within the same population (Lefèvre et al., 2009; Vantaux et al., 2014; Takken and Verhulst, 2017; Busula et al., 2017). Host choice is also influenced by factors such as abundance and availability of hosts as well as mosquito genetic background (Takken and Verhulst, 2013).

Vector role

As already mentioned, mosquitoes play a primary role as vectors of pathogens for human and animal diseases, in particular protozoa of the genus *Plasmodium*, aetiological agents of malaria, and several arboviruses (arthropod-borne viruses) such as West Nile, dengue, chikungunya and Zika viruses (Table 1).

The capacity of a mosquito to be a good vector is a combination of factors: physiological, behavioral and ecological. The interplay among the biological characteristics of vector, host and pathogen defines the prerequisite for a successful transmission cycle of a vector-borne disease. After this, aspects related to the capacity of a mosquito to successfully enter in contact with a specific host, its density, survival and time needed to be infectant for the pathogen are the parameters that transform in a specific context a biologically competent vector in a good vector (Kramer and Ebel, 2003). These conditions change according to the ecology and climate of different habitats in which the mosquito populations are present.

A paradigmatic example is malaria, a parasitic disease caused by protozoan Apicomplexa belonging to genus *Plasmodium* affecting many vertebrate species. Human malaria is caused by five species, four of which are anthroponotic (*P. falciparum*, *P. malariae*, *P. vivax* and *P. ovale*) and one zoonotic (*P. knowlesi*). Despite the enormous efforts in tackling this disease, in the world 228 million cases and 405,000 deaths still occur each year, particularly in sub-Saharan Africa (World Health Organization, 2019a). The human *Plasmodium* parasites are successfully transmitted by only 15% of *Anopheles* mosquito species among the about 460 species described in this genus (Sinka et al., 2012) even if the proportion of competent vectors is much larger. In the most important vectorial system, the *A. gambiae* complex, only some of them are major vectors (*A. coluzzii*, *A. gambiae* s.s. and *A. arabiensis*) due to their large synanthropy, distribution and high anthropophily (Davidson, 1964; White, 1974; Coetzee et al., 2000; Coluzzi et al., 2002). The other species of the complex may have a local role in malaria transmission due to their specific ecological requirements (e.g., *A. merus*, *A. melas*) or even they do not have any epidemiological role (e.g., *A. quadriannulatus*) because of their marked zoophily and a lower degree of competence to the deadliest pathogen *Plasmodium falciparum* (Takken et al., 1999; Habtewold et al., 2008).

Also, mosquito-borne virus threats, which were originally restricted to specific regions, have globally increased in the past decades, with a recent burst in epidemiology and geographic distribution worldwide (Kraemer et al., 2015; Wilder-Smith et al., 2017). The causes of this expansion are multifactorial and strongly associated to the conditions favoring the increasing distribution of the major vectors *A. aegypti* and *A. albopictus*: global trade, uncontrolled urbanization, increase of human population density and movement, inefficient vector control programs (Gubler, 2011; Roiz et al., 2018). Among all the mosquito-borne viruses menacing human health, dengue, yellow fever, chikungunya, Zika and West Nile are the major ones ("WHO Mosquito-borne diseases" www.who.int/neglected_diseases/vector_ecology/mosquito-borne-diseases/en).

Dengue virus (DENV) is nowadays the most common arbovirus, with 390 million cases per year with more than 4000 deaths occurring mostly in central and south America, Indian peninsula and south-east Asia (Bhatt et al., 2013).

Contrarily to DENV, for which the only available vaccine is partially protective (Villar et al., 2015), Yellow fever (YFV) is a virus that has a highly protective vaccine but its availability is limited (Barrett, 2016). This will be the major issue for the control of this virus that is endemic in 33 countries in Africa and 11 countries in South America. YFV has recently demonstrated its capacity to quickly become a resurgent arbovirus, as shown by the outbreak occurred in Angola in 2016 that suddenly requested more than 28 million doses of vaccines, exhausting the existing global vaccine supply (Monath et al., 2016; World Health Organization, 2018).

Table 1 List of major mosquito-borne virus diseases and their major vectors.

Disease	Pathogen(s)	Major mosquito vector(s)	Major reservoir species	Other vertebrate hosts	Geographic distribution	References
Dengue	DENV	<i>Aedes aegypti</i> , <i>Aedes albopictus</i> , <i>Aedes furcifer-taylori</i> , <i>Aedes luteocephalus</i> , <i>Aedes mediovittatus</i> , <i>Aedes niveus s.l.</i> , <i>Aedes opok</i> , <i>Aedes polynesiensis</i> , <i>Aedes scutellaris</i> , <i>Aedes vittatus</i>	Apes, monkeys, humans	Unknown	Africa, South Asia, Central and South America, Oceania	Vasilakis and Weaver (2008)
Zika virus disease	ZIKV	<i>Aedes aegypti</i> , <i>Aedes africanus</i> , <i>Aedes albopictus</i> , <i>Aedes dalzielii</i> , <i>Aedes furcifer-taylori</i> , <i>Aedes hensilli</i> , <i>Aedes luteocephalus</i> , <i>Aedes polynesiensis</i> , <i>Aedes vexans</i> , <i>Aedes vittatus</i> , <i>Culex coronator</i> , <i>Culex quinquefasciatus</i> , <i>Culex tarsalis</i>	Apes, monkeys, humans	Mammals, birds, reptiles, amphibians	Africa, South Asia, Central and South America, Oceania	Gutiérrez-Bugallo et al. (2019) and Sharma et al. (2020)
Yellow fever	YFV	<i>Aedes aegypti</i> , <i>Aedes africanus</i> , <i>Aedes furcifer-taylori</i> , <i>Aedes simpsonii</i> , <i>Haemagogus janthinomys</i> , <i>Haemagogus leucocelaenus</i> , <i>Haemagogus spegazzinii</i> , <i>Sabethes chloropterus</i>	Apes, monkeys	Humans	Africa, Central and South America	Hubálek et al. (2014) and Childs et al. (2019)
Chikungunya infection	CHIKV	<i>Aedes albopictus</i> , <i>Aedes aegypti</i> , <i>Aedes vexans</i>	Apes, monkeys, humans	Squirrels, bushbabies, Bats, rats, Buffalos, elephants	South America, Africa South and East Asia	Guo et al. (2015), Weaver et al. (2018), Mascarenhas et al. (2018)
West Nile infection	WNV, WNVkun	<i>Culex annulirostris</i> , <i>Culex australicus</i> , <i>Culex globocoxitus</i> , <i>Culex modestus</i> , <i>Culex pipiens s. l.</i> , <i>Culex salinarius</i> , <i>Culex tarsalis</i> , <i>Culex univittatus</i> , <i>Aedes albopictus</i> , <i>Aedes annulipes</i> , <i>Aedes cantans</i> , <i>Aedes caspius</i> , <i>Aedes cinereus</i> , <i>Aedes dorsalis</i> , <i>Aedes excrucians</i> , <i>Aedes flavescens</i> , <i>Aedes japonicus</i> , <i>Aedes rossicus</i> , <i>Aedes sticticus</i> , <i>Aedes vexans</i> , <i>Anopheles hyrcanus</i> , <i>Anopheles maculipennis s.l.</i> , <i>Coquillettidia richiardii</i> , <i>Culex territans</i> , <i>Culex theileri</i> , <i>Culex torrentium</i> , <i>Culiseta morsitans</i> , <i>Uranotaenia unguiculata</i>	Birds and rodents	Humans, horses, rabbits, cats, dogs, camelids, amphibians	Cosmopolitan	Prow (2013), Hubálek et al. (2014) and Ciota (2017)
Rift valley fever	RVF	<i>Aedes vexans</i> , <i>Aedes mcintoshi</i> , <i>Culex theileri</i> , <i>Aedes caballus</i> , <i>Aedes circumluteolus</i> , <i>Aedes dentatus</i> , <i>Aedes lineatopennis</i> , <i>Aedes palpalis</i> , <i>Aedes tarsalis</i> , <i>Culex antennatus</i> , <i>Culex pipiens</i> , <i>Culex poicilipes</i> , <i>Culex tritaeniorhynchus</i> , <i>Eretmapodites chrysogaster</i>	Wild and domestic ruminants, rats, bats	Humans, dogs, cats, monkeys	Africa, Yemen, Saudi Arabia	Hubálek et al. (2014) and Linthicum et al. (2016)
Japanese encephalitis	JEV	<i>Culex gelidus</i> , <i>Culex tritaeniorhynchus</i> , <i>Culex vishnui</i> , <i>Culex annulirostris</i> , <i>Culex fuscocephala</i>	Ardeid birds, pigs	Humans, bats, fruit bats, cattle, dogs, goats, rodents	South and East Asia	van den Hurk et al. (2009), Hubálek et al. (2014) and Sudeep (2014)
Usutu infection	USUV	<i>Culex modestus</i> , <i>Culex perexiguus</i> , <i>Culex perfuscus</i> , <i>Culex pipiens</i> , <i>Culex univittatus</i> , <i>Aedes albopictus</i> , <i>Aedes japonicus</i> , <i>Aedes rossicus</i> , <i>Aedes vexans</i> , <i>Coquillettidia aurites</i> , <i>Culex hortensis</i> , <i>Culex territans</i> , <i>Culiseta annulata</i> , <i>Mansonia africana</i>	Birds	Humans, horses, dogs, bats, reed deer	Africa, Europe	Hubálek et al. (2014), Gaibani and Rossini (2017) and Vilibic-Cavlek et al. (2019)

Bunyamwera orthobunyavirus (Batai virus) infection	BUNV	<i>Anopheles claviger s.l.</i>, <i>Anopheles messeae s.l.</i>, <i>Coquillettidia richiardii</i>, <i>Aedes communis</i>, <i>Aedes punctor</i>, <i>Aedes vexans</i>, <i>Culex pipiens</i>, <i>Culiseta annulata</i>	Pigs, horses, ruminants	Humans, birds	Eastern Europe, Asia, Africa	Lvov et al. (2004), Hubalek (2008), Calzolari et al. (2016), and Napp et al. (2018)

In “Major mosquito vector(s)” column the primary vector species are highlighted in bold.

Chikungunya virus (CHIKV) spread out from its original African distribution in 2004, causing epidemics in several islands of Indian Ocean, India, Southeast Asia, China, reaching Europe in 2007 and finally Caribbean and Latin America in 2013–14 (Rezza et al., 2007; Kariuki et al., 2008; Grandadam et al., 2011; Khan et al., 2014; Weaver and Lecuit, 2015; Riccardo et al., 2019).

Zika virus (ZIKV) is the most recent example of global spreading: isolated for the first time about 70 years ago in Uganda on a *Rhesus* monkey and subsequently on *Aedes africanus* mosquito (Dick et al., 1952; Macnamara, 1954). The occurrence of the virus was limited in African continent until 2007, when an outbreak was recorded in the Federated States of Micronesia (Hayes, 2009). In 2013–15 the virus reached Brazil, subsequently spreading throughout central and south America (Musso et al., 2014; Brito and Cordeiro, 2016; Brasil et al., 2016; Baud et al., 2017).

All the above-mentioned viruses are transmitted in urban or periurban areas mainly by *A. aegypti* and *A. albopictus*, while in sylvatic conditions are transmitted in zoonotic cycles involving non-human primates and forest-associated *Aedes* mosquitoes (Kramer and Ebel, 2003; Hanley et al., 2013; Benelli and Romano, 2017; Braack et al., 2018).

The last example, West Nile virus (WNV), has a life cycle different from the above-mentioned arboviruses. WNV is a cosmopolitan arbovirus, isolated for the first time in Uganda in 1937 (Smithburn et al., 1940), which from early 1990s rapidly increased its distribution in the Europe and Asia (Hayes, 2001) and subsequently throughout North and South America (Lanciotti et al., 1999; Ebel et al., 2001; Hayes et al., 2005). WNV is maintained in nature by ornithophilic mosquitoes, mostly belonging to *Culex* genus, and wild birds (Hubalek, 2008; Rizzoli et al., 2015). Only in North America, about 60 and more than 280 mosquito and bird species, respectively, have been found infected from the virus (Hayes et al., 2005; Kain and Bolker, 2019). Other than birds and mosquitoes, in which the natural cycle of WNV occurs, it can infect a broad range of vertebrates (including amphibians, reptiles and mammals), showing to be a virus ecologically more generalist than other arboviruses (Kramer et al., 2008). This occurs when, during late summer, the avian preferred hosts of vector mosquitoes become less abundant. Then, ornithophilic mosquitoes shift their feeding behavior toward other species, mammals in particular, as observed for *C. pipiens* in the United States (Kilpatrick et al., 2006). However, despite the virus is particularly pathogenic for horses and humans, these are “dead-end hosts” for WNV, as the viraemia does not reach levels sufficiently high to infect mosquito vectors (Pérez-Ramírez et al., 2017).

Dispersal and invasiveness

The adult mosquitoes move around the environment for different needs, trophic and related to the resting and oviposition sites, with marked differences among species. Some mosquitoes have a very narrow range of action, tens or hundreds of meters, while others can move even over distances of kilometers (Service, 1997; Clements, 1999). This intrinsic characteristic is then modulated by extrinsic factors, both ecological and climatic, such as distribution patterns of vegetation and potential hosts, infective status, seasonal conditions affecting temperature, rainfall, etc. (Reisen et al., 2003; LaPointe, 2008; Gu and Novak, 2009; Hemme et al., 2010; Newman et al., 2016). Complementarily to the above mentioned active dispersal, some mosquito species can successfully exploit (intentionally or not) passive means of dispersal, essential for long-range distributions. Increased global trade, transports and mobility of people, together with concomitant climate and environmental change, have increased the chances of mosquito species to spread and adapt to new areas (Laird, 1984; Daszak et al., 2000; Lounibos, 2002; Juliano and Lounibos, 2005; Jones et al., 2008). According to Juliano and Lounibos (2005), “invasive” mosquitoes are species introduced to new environments that have increased and spread, creating the potential for impacts on native species and ecosystems or on human activities (agriculture, conservation). These mosquitoes have a large ecological niche breadth, which allows them to quickly adapt to a wide range of new environments, from natural to highly anthropized habitats. They may expand into new geographic contexts by filling an empty or unsaturated habitat or exploiting a previously unused resource (Williamson, 1996).

Their major ecological characteristics are: a wide range of temperature tolerance, diapausing strategies, often through drought-resistant eggs, allowing the exploitation human transportation channels (Hawley et al., 1989; Lounibos, 2002; Benedict et al., 2007; Eritja et al., 2017; Maynard et al., 2017; Sherpa et al., 2019; Wilke et al., 2020), and the capacity to breed in small, artificial water habitats (Vezzani, 2007). These features are common in invasive mosquitoes, despite not essentially present all together (Juliano

Table 2 List of invasive species that successfully established in countries out from their geographic distribution of origin.

Species (origin)	Invaded/colonized region	Macrohabitat preference	Larval habitats	Desiccation-resistant eggs	Diapause	References
<i>Aedes aegypti</i> (Africa)	Cosmotropical	Urban, domestic	Man-made containers	Yes	None	Kraemer et al. (2015)
<i>Aedes albopictus</i> (temperate and tropical Asia)	Americas, Europe, Africa, Oceania	Urban, suburban	Phytotelmata, man-made containers	Yes	Egg	Kraemer et al. (2015)
<i>Aedes atropalpus</i> (N. America)	Europe	Riparian	Rock pools, man-made containers	Yes	Egg	Scholte et al. (2009)
<i>Aedes j. japonicus</i> (temperate Asia)	North America, Europe	Rural, sylvan	Rock pools, man-made containers	Yes	Egg	Kaufman and Fonseca (2014)
<i>Aedes notoscriptus</i> (Australia)	New Zealand, United States	Urban, suburban, rural	Tree holes, rock pools	Yes	Egg, larva	Peterson and Campbell (2015)
<i>Aedes koreicus</i> (temperate Asia)	Europe	Suburban, rural	Man-made containers	Yes	Egg	Medlock et al. (2015)
<i>Aedes togoi</i> (temperate Asia)	North America	Urban, suburban	Coastal rock pools, artificial containers	Yes	Egg, larva	Belton (1980)
<i>Culex pipiens</i> (Old World)	North America	Urban, domestic, suburban	Man-made containers, subterranean, small groundwater pools	No	Adult	Vinogradova (2000)
<i>Culex quinquefasciatus</i> (Africa)	Americas, Asia, New Zealand, southern Europe	Urban, domestic, suburban	Man-made containers, small groundwater pools	No	None	Vinogradova (2000)
<i>Culex panocossa</i> (Central and South America)	United States	Suburban, rural	Natural water bodies	No	None	Blosser and Burkett-Cadena (2017)
<i>Culex coronator</i> (Central America)	South America, United States	Urban, domestic, suburban	Rock pools, tree holes, man-made containers	No	None	Akaratovic and Kiser (2017) and Wilke et al. (2020)
<i>Anopheles stephensi</i> (tropical Asia and Middle East)	Djibouti, Ethiopia	Urban, domestic, suburban	Man-made containers, small groundwater pools	No	None	Carter et al. (2018) and Seyfarth et al. (2019)

The criterion of establishment is based on subsequent observations in a new environment for at least two reproductive seasons.

and Lounibos, 2005). Among these mosquitoes, species belonging to the genus *Aedes* have the ecological characteristics that make them particularly suitable for spreading and colonizing new areas (Table 2).

The spreading success of the two major invasive mosquitoes, *A. albopictus* and the closely related *Stegomyia* species *Aedes aegypti* (major vectors of DENV, ZIKV, CHIKV, and YFV), is an example of how niche expansion of these two mosquitoes allowed the geographic spread from their respective native ranges of Asia and Africa to a worldwide diffusion (Kraemer et al., 2019). Their trophic behavioral change from zoophily to anthropophily and larval adaptation from natural small water sources to artificial containers in domestic habitats is the key feature that allowed this spread (Powell and Tabachnick, 2013; Powell, 2016). Recent models show that these two species will not stop their diffusion to new areas, particularly in urban settings, filling unoccupied suitable habitats and increasing the risk to human health (Kraemer et al., 2019).

In particular, the world's most invasive mosquito, *A. albopictus*, is a species that is able to actively disperse only a few hundred meters (Marini et al., 2010; Marini et al., 2019a,b; Gouagna et al., 2015; Medeiros et al., 2017; Vavassori et al., 2019) but, despite its not exceptional flying capacity, this mosquito has been capable to reach all continents. It is a species native to South-East Asia which, given its extreme aggressiveness, opportunistic feeding behavior (Savage et al., 1993; Delatte et al., 2010; Valerio et al., 2010) and ability to transmit several pathogens, is one of the species of greatest interest to the scientific community. Its capacity of diffusion and colonization of different anthropized habitats exploiting trade in items such as tyres and potted plants (Paupy et al., 2009), coupled with the capacity to establish in temperate areas thanks to a diapause strategy at egg stage (Vega-Rua et al., 2013; Armbruster, 2016), led *A. albopictus* to become the second most abundant species after *Culex pipiens*, particularly in urban areas of European and Mediterranean countries ("ECDC Mosquito maps," www.ecdc.europa.eu/en/disease-vectors/surveillance-and-disease-data/mosquito-maps).

Another important invasive mosquito is *Aedes japonicus*, a container-breeding species endemic of temperate Eastern countries (Tanaka et al., 1979) and now present in several areas of Europe, North America and New Zealand (Medlock et al., 2015). As already observed for *A. albopictus*, *A. japonicus* is spreading by continuous importation of goods and a subsequent dispersal through active

flight and possibly passive transports by human activities (Kampen and Werner, 2014; Koban et al., 2019). It can reproduce in a wide variety of environments, both artificial and natural (Crans and McNelly, 1999; Schaffner et al., 2009; Kampen and Werner, 2014; Sáringier-Kenyeres et al., 2020). Compared to other invasive species, it is even more tolerant to low temperatures and its resistant eggs can survive to very cold winters. This characteristic led *A. japonicus*, together with another invasive mosquito in Europe with similar ecology, *Aedes koreicus* (Montarsi et al., 2013), to be a species ecologically complementary to *A. albopictus* in temperate areas (Cunze et al., 2016; Koban et al., 2019; Marini et al., 2019a,b). Moreover, *A. japonicus* is a competent vector of several arboviruses (Veronesi et al., 2018; Abbo et al., 2020), increasing the list of invasive vectors threatening the health of human population worldwide.

The species described so far are morphologically very similar to each other (Fig. 3), then difficult to identify if not by specialized personnel. The continuous arrival of new mosquito species in a specific context is therefore, a problem of great importance in terms of surveillance of disease vectors, in which appropriate sampling approaches and the constant and capillary monitoring of the territory are fundamental to detect their presence at an early invasion stage.

The invasion of new territories by mosquitoes is possible not only by the involvement of human activities but also exploiting natural phenomena. A spreading strategy that is receiving more attention among medical entomologist is the wind-assisted long-distance dispersal. According to Service (1997), wind-assisted strategy in mosquitoes was not considered as migration, because there is no convincing evidence that this taxonomic group purposely fly downwind to colonize new areas and subsequently they, or their progeny, return. However, new information is raising on this topic and some new evidence of migratory events are now available also for mosquitoes. A seminal study recently published by (Huestis et al., 2019) describes for the first time that wind-assisted dispersion can occur in the major malaria mosquitoes of the *A. gambiae* complex. Through the usage of helium balloons, mosquitoes were collected by sticky nets between 40 and 290 m a.s.l. for about 2 years of sampling. Among all the 461,000 insects collected, 0.6% were mosquitoes, including blood-fed *Anopheles* females. The model built from these data indicates that malaria-bearing mosquitoes can travel for several kilometers in a single night, with an estimate of about 6 million *A. coluzzii* and 81,000 *A. gambiae* s.s. able to travel each year for 100 km across regions. The long-distance travel strategy described in this study suggests that malaria transmission dynamics can be more complex than expected, considering the potential genetic exchange of *Anopheles* and *Plasmodium* populations between distant areas carrying, respectively, insecticide and drug resistant genes, with potentially dramatic consequences for malaria control strategies.

Surveillance, monitoring and control

Mosquito-borne pathogens are increasing their distribution, with consequent worsening of their impact on public health. Therefore, surveillance systems are mandatory to prevent and tackle mosquito-borne diseases. Entomological surveillance follows a path in which the identification of an arthropod-borne pathogen, the presence and abundance of its potential vectors through standardized monitoring and characterization, and finally the realization of control campaigns are integrated and harmonized according to the different ecological contexts (Jourdain et al., 2019):

- (1) Risk assessment: prioritization of public health threats
- (2) Early warning systems
- (3) Identification of the vector species involved in a transmission event

Fig. 3 Example of morphological details of head and thorax of four morphologically similar *Aedes* mosquitoes that can be collected in sympatry: (A) *Aedes aegypti*, (B) *Aedes albopictus*, (C) *Aedes koreicus*, and (D) *Aedes japonicus*.

- (4) Identification of the circulating pathogen strain
- (5) Optimizing vector control in time and space
- (6) Guidance for source reduction campaigns
- (7) Insecticide resistance monitoring
- (8) Evaluating the efficacy of vector control

Integrated Vector Management (IVM) is often the only means available to reduce the incidence of mosquito-borne diseases for which effective treatments or vaccines are not available yet. This imposes the use of all tools available and requires research efforts to develop novel technologies, of which the appropriate use depends on the eco-epidemiological contexts to maximize the impact on disease transmission (Benelli and Beier, 2017; Wilder-Smith et al., 2017; Achee et al., 2019).

The first aspect to be addressed is the estimation of mosquito presence and density. This is achieved through specific monitoring approaches, aiming to collect eggs, larvae or adults according to the different target species. Eggs and adults, in particular, are the mosquito stages that can be collected with trapping approaches, while larvae are usually collected by sampling in breeding sites. The choice of the sampling approach (e.g., type of trap, numbers, location etc.) must be carefully evaluated because it has an important influence on the success of the catches and therefore the affordability of the monitoring system. It is also important to standardize the sampling approach to have geographically and temporally comparable data.

Among the several trapping methods available (Silver, 2008), we here cite just a few examples. The ovitrap is the method traditionally used to sample container-breeding mosquitoes belonging to *Aedes* genus. It consists of a black plastic pot, filled with water, in which is placed a wooden stick. The trap exploits the propensity of *Aedes* mosquitoes to lay their eggs on wet substrates (the wooden stick) in a water container. A limitation of this approach is that the number of eggs laid by a single female can be highly variable, thus affecting population density estimates. Some variants of this approach, based on sticky surfaces, have been developed to collect gravid females instead of eggs (e.g., Facchinelli et al., 2007; Lee et al., 2013). Another method to collect ovipositing mosquitoes, in particular *Culex spp.*, is the gravid trap (Di Menna et al., 2006), which actively aspirate mosquitoes attracted by the water container present in the trap. The attractiveness of all these traps can be increased using plant infusions that simulate a suitable oviposition site. Among the sampling approaches for the monitoring of resting mosquitoes, traps have been only recently developed. This is particularly useful for *Anopheles* mosquitoes, where indoor-outdoor sampling based on active aspirations are affected in terms of standardization by the ability of the operator and by the characteristics of the site. Some examples for this genus are the clay pots (Odiere et al., 2007) and the resting box and bucket (Kweka et al., 2009; Pombi et al., 2014; Kreppel et al., 2015). However, the most targeted fraction of mosquito populations are the host-seeking females. This because they are the closest proxy to the actual numbers of mosquitoes biting a host and, consequently, to the risk of disease transmission. Apart from landing catches, which consists in catching mosquitoes that try to land on the collector and are consequently the better estimate of the biting pressure (Service, 1977), several traps are available. Among these, which show different performances on the several species targets, the CDC light trap and the BG-Sentinel are by far the most used. Both traps actively aspirate the mosquitoes that are attracted, respectively, by a light source or a dark-white pattern coupled with an odor blend. The number of mosquitoes and species collected by both traps increases using a source of CO₂ as attractant. Despite the large number of species that CDC light trap and BG-Sentinel can collect (Drago et al., 2012; Pezzin et al., 2016), the CDC light trap is considered a gold standard for nocturnal species, *Culex* and *Anopheles* in particular, while the BG-Sentinel for daytime biting mosquitoes, *Aedes* above all.

Of note, monitoring mosquito vectors is an essential activity to not only evaluate the presence, abundance and diffusion of a target species as part of an entomological surveillance system but also to assess the effectiveness of vector control actions in terms of reduction of mosquito density, host-vector contact and pathogen infection levels.

For more than a century vector control has been the major preventing strategy of vector-borne diseases and continue to be in several cases the only option available (Wilson et al., 2020). To date, many tools of mosquito control have been developed, which can be classified as: environmental, biological, mechanical, chemical and genetic.

Environmental control methods are those activities that are part of good prevention practices, tailored on ecology and behavior of the species target. Larval habitat removal is one of the major environmental intervention. As an example, in urban areas where the major source of container-breeding mosquitoes are the peri-domestic habitats, removal/emptying of containers that could retain water and covering large containers with nets or lids are particularly useful in reducing mosquito density.

One of the simplest biological control methods is the introduction of natural predators such as fish (e.g., Poeciliidae) or copepods (e.g., *Macrocyclus*, *Mesocyclops*) in the larval breeding site (Benelli et al., 2016). This is possible in medium-large permanent water collections, where pollution is at low levels. When this is not feasible, biological larvicides can be used, which are harmless to other non-target animals, particularly vertebrates. The most common biological larvicides, highly specific for mosquito larvae, are bacteria of the genus *Bacillus* such as *B. thuringiensis* var. *israelensis* and *B. sphaericus*. However, their persistence is limited and require repeated treatments. Another biological control approach is based on the usage of entomopathogenic fungi (Kanzok and Jacobs-Lorena, 2006). These moulds, such as those belonging to the species *Beauveria bassiana* (Clark et al., 1968; Achonduh and Tondje, 2008; García-Munguía et al., 2011) and *Metarhizium anisopliae* (Scholte et al., 2004, 2007), have shown in laboratory conditions to be selective and versatile mosquito control tools that can be added on surfaces where mosquitoes lay eggs, on clothes, fabrics or mosquito nets (Lovett et al., 2019).

Mechanical control methods are represented using monomolecular films. This approach is particularly useful if the size of the larval site is rather large and the larvicidal treatment would require considerable amounts of product or the effectiveness of the larvicide/predator is limited by the organic water pollution. The monomolecular films are apolar products that are poured in drops

onto the water surface to create a thin film that reduces surface tension. This prevents the larvae from breathing properly and the mosquito adults (e.g., *Culex*, *Anopheles*) from laying their eggs on the surface (Nayar and Ali 2003; Ngrenngarmlet et al., 2016).

The most used mosquito control approaches are chemical insecticides. Five major classes of insecticides are used against vector mosquitoes: pyrethroids, organochlorines, organophosphates, carbamates, neonicotinoids (World Health Organization, 2019b). To the above-mentioned classes, insect growth regulators (IGR) must be added to the list as larvicides only, even if several effects also on adults, particularly on fecundity, have been described (Mbare et al., 2014; Yadav et al., 2019). While for *Anopheles* malaria vectors adulticides are recommended in terms of epidemiological impact (World Health Organization, 2019b), in the case of *Culex* and *Aedes* arbovirus vectors the usage of chemical larvicides, IGR in particular, is far more common (World Health Organization, 2013).

When used outdoors, chemical adulticide interventions are aimed at drastically lowering the density of adult mosquitoes, but it should always be kept in mind that the knockdown and lethal effects of the treatment, even if carried out applying good practices, are limited in time (a few days). Among the several insecticide formulations for the control of adult mosquitoes, the most common are pyrethroids. Particularly in urban areas, adulticide treatments are conducted outdoors using large-scale sprayers/nebulizers/foggers able to produce a mist of microdroplets with a high dispersal capability. On the other hand, the indoor usage of chemical adulticides for vector control is split into two major approaches: Insecticide Treated Nets (ITNs) and Indoor-Residual Spraying (IRS): ITNs in particular have demonstrated to be highly effective in reducing the malaria burden at global scale (Bhatt et al., 2015; Wangdi et al., 2018). Several ITNs are available on the market, most of them are Long-Lasting Insecticidal Nets (LLINs) impregnated with pyrethroids that can contain or not the synergist piperonyl butoxide (PBO) ("WHO Vector Control," www.who.int/vector-control/vcag/new-interventions/en/index1.html). According to WHO indications, recommended ITN are bednets manufactured in compliance with standards of efficacy, safety, and quality ("WHO New types of insecticide-treated nets," www.who.int/news-room/q-a-detail/new-types-of-insecticide-treated-nets; "WHO Prequalification Team: Vector Control Products," www.who.int/pq-vector-control/en). They are expected to be effective in terms of insecticidal content and durability for at least 3 years or 20 washes. These are most effective against nocturnal, indoor-biting species such as *Anopheles* malaria vectors. The IRS strategy is based on the aspersions of a residual insecticide to mosquito resting surfaces (e.g., house walls and ceilings, animal shelters). The efficacy of this treatment is expected to last several months, according to the product used. In both cases, the insecticidal activity occurs when mosquitoes come into contact with the insecticide-impregnated surface, knocking-down or killing them in a short time-frame.

IGRs act on larvae by altering their development, preventing metamorphosis into adult. Contrarily to the other chemical insecticide classes, these are slow-acting, leading to the death of the insect at the end of the larval stage. Among the active ingredients available, one of the most used is pyriproxyfen (Maoz et al., 2017).

The major threat to the efficacy of chemical compounds is insecticide resistance, which raised in most of the mosquito vectors and currently spreading worldwide (Fig. 4; World Health Organization, 2012; Liu, 2015; Hemingway et al., 2016; Ranson and Lissenden, 2016; Riveron et al., 2018). Multiple resistance mechanisms are known to undermine insecticide-based control approaches in mosquito species (Liu, 2015; Ingham et al., 2018; Riveron et al., 2018), ranging from mutations conferring target site insensitivity (e.g., sodium channel, acetylcholinesterase, GABA receptors) to overexpression of metabolic detoxification systems (cytochrome P450s, esterases, glutathione S-transferases) or cuticular hydrocarbon alterations (Balabanidou et al., 2019) and chemosensory proteins overexpression (Ingham et al., 2020). To these genetic and morpho-physiological factors are also included behavioral mechanisms of resistance to insecticides, which concur to reduce lethal contact to insecticides and thus their effectiveness (e.g., increased exophily, opportunistic biting activity and/or shift in biting activity; Killeen, 2014; Carrasco et al., 2019).

Several alternative control approaches based on combinations of the above mentioned methods have been developed, e.g., autocidal gravid ovitraps (Mackay et al., 2013; Barrera et al., 2017; Cilek et al., 2017; Liu et al., 2019), autodissemination (Devine et al., 2009; Caputo et al., 2012; Gaugler et al., 2012; Swale et al., 2018; Brelsfoard et al., 2019; Lwetoijera et al., 2019), ultrasonics against larvae (Britch et al., 2016; Kalimuthu et al., 2020), spatial repellents (Grieco et al., 2007; Choi et al., 2011; Ogoma et al., 2014; Norris and Coats, 2017; Mwanga et al., 2019), attractive toxic sugar baits (Fiorenzano et al., 2017; Traore et al., 2020). However, further optimizations of these approaches are ongoing and their potential impact in vector control should be considered complementary to the existing strategies (Achee et al., 2019).

Finally, the last frontier of vector control is represented by modified mosquitoes, which consist of manipulation techniques of mosquito populations based on different approaches that can be grouped in two major categories: population suppression and population replacement (Flores and O'Neill, 2018; Wilke et al., 2018).

Sterile Insect Technique (population suppression): Through radiation or chemical treatment, male mosquitoes are rendered sterile. These males are released in the field to compete with wild-type males for mating with natural females. If a large number of females mate with the sterile males, they will be unable to produce viable offspring, thus reducing mosquito population density. This is not a novel approach (Dame et al., 1974; Weidhaas et al., 1974) and has the limit to oblige continuous release of males in the field. However, SIT continues to be developed as it still has promising potential, mostly thanks to the optimization of mosquito irradiation approaches and mass-rearing protocols (Balestrino et al., 2010; Bellini et al., 2013a,b).

Dominant Lethal Transgene (population suppression): Males carrying a dominant transgene that causes lethality at the larval stage are released in the field. When these males mate with wild-type females, the resulting progeny, which is heterozygote for the transgene, die before reaching the pupal stage.

Incompatible Insect Technique (both population suppression and replacement): It is based on the usage of *Wolbachia*, a genus of intracellular gram-negative bacteria that naturally infect some insect species, including some mosquitoes, and transmits vertically to the progeny by infecting eggs. Its presence modulates fitness in the population as confers a frequency-dependent fitness through a

Fig. 4 Worldwide geographic distribution of pyrethroid insecticide susceptibility of (A) *Aedes albopictus* and *Aedes aegypti*, (B) *Anopheles* spp. Red dots: confirmed insecticide resistance; Yellow dots: possible insecticide resistance; Green dots: insecticide susceptibility.

mechanism of cytoplasmic incompatibility: crosses between *Wolbachia*-infected males and wild-type females are unviable. The exploitation of this mechanism is at the base of *Wolbachia*-release strategies. The sterility can occur also when infected males mate with wild-type females carrying a different, incompatible strain of *Wolbachia*. Moreover, the introduction of specific *Wolbachia* strains in a natural population can lead to refractoriness of the mosquitoes for a pathogen (e.g., *A. aegypti* and dengue virus) (Moreira et al., 2009; Walker et al., 2011). Thanks to the characteristic of *Wolbachia* to guarantee the progeny only of individuals carrying the bacteria, the whole mosquito population become infected by *Wolbachia* and contemporarily unable to transmit the pathogen.

Gene drive (both population suppression and replacement): is a method of genetic modification that can be used to spread a desired phenotype through the mating of the natural population with released modified mosquitoes (Gabrieli et al., 2014; Adelman, 2015; Hammond and Galizi, 2017). The gene drive technologies have the advantage to potentially introduce modified mosquitoes in wild-type populations through a limited number of releases and quickly rise to high frequencies. This allows desired transgenes to spread through populations in a self-sustaining manner, even if they confer a fitness cost. Several gene drive systems have been described and laboratory tested (Marshall and Taylor, 2009; Adelman and Tu, 2016), but the two most developed technologies are homing endonuclease genes (HEG) and CRISPR–Cas9. These approaches are based on an endonuclease that recognizes a specific DNA sequence and catalyses a break. The DNA is then naturally repaired through homology-directed repair, using as a template the sequence present in the other chromatid. This occurs during mitosis of germline cells or meiosis, leading to a non-Mendelian inheritance of the desired character. This technique theoretically allows a quick, complete replacement of the natural population with the new phenotype. However, the epidemiological impact of GM-based mosquito control tools is still debated (Wilke et al., 2018).

Wolbachia and gene drive vector control approaches have the potential to be game-changer in mosquito-borne disease epidemiology, giving long-term reductions in pathogen transmission after only a single implementation period, by stable reductions in mosquito density or vector competence (Ferguson, 2018). However, most of the above mentioned new approaches are still in the early phases, and only *Wolbachia*-based approaches are being utilized at operational scales in medium-sized cities (Flores and O'Neill, 2018).

Concluding remarks

The control of mosquito-borne diseases is a far-off goal that we will never be able to achieve unless we adopt a holistic view of the problem, through a One Health approach. Human and animal hosts, pathogens and their vectors are interconnected elements of a single ecological system that needs to be fully known in relation to each of these diseases. Current and future vector control strategies, to be effective, must necessarily identify all the actors involved, acting on multiple levels through an IVM approach. In this long arms race between humans and mosquitoes, we must not forget the importance of being part of a complex ecological network in which the introduction of a disturbing element can have unexpected consequences that must be evaluated in as much detail as possible. The application of each control tool could have advantages in terms of immediate effectiveness but may present threats that need to be considered through a weighted analysis of risk assessment. The current resistance to insecticides is an example of how the resilience of several mosquito species to this selective factor has allowed them to react in many ways, undermining our ability to control the diseases they transmit, malaria above all. There is no doubt that we will never stop cohabiting with this ancient enemy, precisely because we have always shared the same house and neither of us wants to be kicked out.

Glossary

Autogeny Production of batch(es) of eggs before first blood meal.

Bartonellosis Biphasic disease caused by *Bartonella bacilliformis*, causing anemia and warts, potentially mortal.

Cibarium A dilatation of alimentary tube, visible in the head, visible from venter of clarified flies, containing teeth and dark areas.

Gonotrophic concordance Synchronization between a blood meal and production of a batch of eggs.

Kairomone Substance from any source that influences animals of a different specie at a distance.

Leishmanization Injection of live *Leishmania* in a hidden part of the body, to prevent lesions in an exposed part, mostly the face.

Palpus Maxillary palpus, with five subsegments, the second one fused to first, in sand flies.

Pheromone Substance produced by and animal that influences a member of the same specie at a distance.

Solenophages Insects that suck blood direct from capillary, having long and well developed mouth parts.

Spermatheca A reservoir for spermatozoa, found in females of sand flies and very variable in form.

Telmophages Insects that suck blood from subcutaneous pools, caused by lesions made by mouthparts, which are short or for other reasons non-adapted to suck from capillaries.

Introduction and history

Phlebotomine sand flies (sandflies in British English) are small Diptera widely distributed, mostly in tropical and subtropical areas, but also in temperate regions, like the South of France and some areas in Germany and Switzerland.

The first known reference to leishmaniasis was in a clay tablet in the library of the Assyrian king Ashurbanipal in Nineveh (now Mossul, Iraq). Ibn Sīnā (Avicenna, 980–1037) described cutaneous leishmaniasis. Gorgani (1042–1136) called it in Persian “pashé gazidegui” (“bitten by the mosquito”), and *saalak* (“one-year sore”), the last still utilized in Iran. Also, the transmission of

Leishmania by sand flies was suspected by some Andean people several centuries ago, naming the flies and leishmaniasis by *uta*, and Cosme Bueno cited the transmission of (agents of) Carrión disease and leishmaniasis in 1764 (Herrer and Christensen, 1975).

In the beginning of 20th century, first species of *Leishmania* were described, and many blood feeding animals (except leeches and vampire bats) were tested, finally concentrating on sand flies. Researches were developed mostly in India, and also in Brazil, where H. B. Aragão transmitted *L. braziliensis* to dogs by injection of infected *Nyssomyia intermedia*¹ in 1922, and other countries. Efficient transmission by bite only was obtained after feeding infected insects on sugar from raisins, in 1940s (Killick-Kendrick, 2013).

An outbreak of a biphasic disease in the Andes region, during the building of the railway Lima-Oroya, in 1871, caused at least 4000 deaths among workers, and it was called Oroya fever. A medicine student, Daniel Carrión, injected himself with exudate from a wart ("verruca" in Spanish), developed Oroya fever and died. The common etiology of both diseases was established and the infection was called Carrión disease, in homage to the heroic Peruvian researcher. In 1905, the causing bacterium was described by Alberto Barton from blood smears of patients. Transmission by sand flies was first demonstrated in 1913 by C. H. T. Townsend, which described its major vector, *Pintomyia verrucarum* (= *Phlebotomus verrucarum*).

The exclusive observation of external characters, like scales and dimensions of appendices, produced several incomplete descriptions, like those of *Lutzomyia longipalpis*, *Ny. intermedia* and *Psychodopygus squamiventris* (all in *Phlebotomus*) based mostly on the length of palpi and the presence of scales on the abdomen (Lutz and Neiva, 1912). The study of internal structures, after Adler and Theodor's (1926) observation of spermathecae and their ducts and cibarium of females, gave big boost for classification and description of new species, and there are now at least 1000 described species in the world. Description of new species in previously unstudied areas, like the Highlands of Madagascar (Randrianambinintsoa et al., 2019) will certainly enlarge this number.

Recently, new and potentially useful structures have been added to descriptions (Galati et al., 2017; Galati, 2018), and molecular biology has been much utilized for characterization and differentiation of species. Recent description of *Trichophoromyia velezbernalei* (Posada-López et al., 2018) is an example of utilization of those structures for the differentiation of species.

Other ca. 2000 species of Psychodidae are distributed among five subfamilies (Pape et al., 2011). Some species of these so-called moth flies (or owl flies) may be annoying, mostly near sewage treatment sites, and contribute to contamination in hospitals, cause allergy or opportunistic myiasis. Several psychodids of Sycoracinae (*Sycorax* - 45 spp.) (Santos et al., 2013) have bloodsucking mouthparts, some of them biting Amphibians and even transmitting filariae.

Morphology and taxonomy

Adults

Sand flies are small (length — 2–3 mm) hairy Diptera, constituting Phlebotominae in Psychodidae, which belongs to suborder Psychodomorpha, one of eight orders in Diptera; due mostly to their long and multiarticulate antennae,² this family used to be included in Nematocera, now considered as a paraphyletic group.

Legs are long, lanceolate wings are maintained erect over the body, when landing, and head and thorax are in 90° angle (Figs. 1 and 2). Wing transversal veins are restricted to basal half and all ramifications of vein R_s (R₂-R₄) reach the border of the wing.

Fig. 1 Adults of *Phlebotomus papatasi* in copula. Right – male. Courtesy of CDC (photo – Edgard Rowton).

¹They could be *Ny. whitmani*, described in 1939 and present in forested areas of the city (N. A. Souza – pers. commun.), one of them near that locality ("Águas Ferreas") (Souza et al., 2015). The locality had in 1922 many trees and was humid, and cases of cutaneous leishmaniasis were widely distributed.

²Antennae of all insects have three segments, and the most distal (flagellum) may be divided in subsegments (or annuli), which have no implantation of musculature (Snodgrass, 1993).

Fig. 2 Adults of *Lutzomyia longipalpis*. In black rectangle: couple in copula, male below. Courtesy of Nataly A. Souza.

For males, the study of genitalia, including the length of sperm pump and length, shape and tips of aedeagal ducts, number and localization of spines on gonostyle, non-deciduous hairs and shape of gonocoxite, parameres and epandrial lobes (=lateral lobes) are important for identification (Galati, 2018).

For females, shape of spermathecae and ducts (individual and common) and cibarial teeth are very important. Other structures potentially useful were listed by Galati et al. (2017) and thoroughly described by Galati (2018).

Immature forms. Eggs are oval or ellipsoid (0.3 to 0.5 mm in length/0.07 to 0.15 mm width); when laid, they are whitened or yellowed, and in hours become dark brown (Brazil and Brazil, 2015). Their exochorium present structures not yet well studied in many species, probably due to fragility of eggs (J. Santos-Mallet – pers. commun.).

Larvae are wormlike and have distinct black head, three thoracic and nine abdominal segments; first instar larvae have two posterior long setae, and four are (in most species) present in the other three instars³ (Figs. 3 and 4). External structures are potentially useful for identification and deserve additional studies; detailed description of larvae and pupae of the important species *Ny. umbratilis* (Alencar et al., 2018) is an example for these studies. Pupae are fixed to the substrate by larval exuvia (Fig. 4) and have flexion and extension movements when disturbed (Brazil and Brazil, 2015).

Fig. 3 Larva of *Lutzomyia longipalpis*. Courtesy of Reginaldo P. Brazil.

³The only known reference to the function of these long setae was done by M. P. Barretto in a thesis in 1942, reporting their utilization to expel mites from their bodies.

Fig. 4 Larvae and pupae (indicated by red arrows) of *Lutzomyia longipalpis*. Courtesy of Reginaldo P. Brazil.

Taxonomy. They have been organized in 31 genera and 35 subgenera (Galati, 1995, 2018), most of them in the American continent. Special abbreviations for genera and subgenera were proposed (Marcondes et al., 2007) and have been widely utilized. Akhoundi et al. (2016) revised the history of classification, evolution and dispersal of *Leishmania* and sand flies.

Although there is not a strict association between phylogeny and biology and vectorial role, which are influenced by several factors (Ready, 2011), this classification has been shown to be reliable and useful. A review of molecular taxonomy studies on sand flies, comparing isoenzymes, cuticular hydrocarbons and DNA sequences (Depaquit, 2014) emphasized the concentration on medically important species; those techniques were indicated as less laborious and probably more productive and useful than morphology, mostly if utilized with due care. The only limitation would be the availability of material and equipment, usually expensive.

Evidence of genetic divergence and cryptic speciation by reproductive, morphological, isoenzyme, biochemical, and genetic traits (Soto et al., 2001; Arrivillaga et al., 2002, 2003; Hamilton et al., 2005; Pech-May et al., 2018) have shown that *Lu. longipalpis* is a species complex, whose components should be formally described (Brandão-Filho et al., 2009).

Mitochondrial DNA of several vectors of *L. major* around the Mediterranean was studied to understand phylogeography and coevolution of protozoa and sand flies (Esseghir et al., 1997).

Illustrated keys for both sexes of American species were provided by Galati (2018), and a digital key for Brazilian species, adapted to cell phones, was built by Rocha et al. (2019).

Biology and ecology

Biology

Based on laboratory studies, blood-fed females lay ca. 30–70 eggs (Lawyer et al., 2017). They are laid on wet and dark places on the soil, in a great variety of habitats (34 types): under stones and decomposing leaves, near tree roots, in caves, rodent burrows and bird nests etc. (Feliciangeli, 2004).

Breeding places for sand flies may also be in human-modified places, like the contaminated soil of animal shelters for medically important *Lu. longipalpis* in the New World, *Ph. argentipes* in India, *Ph. chinensis* in China and *Ph. ariasi*, *Ph. perfiliewi* and *Ph. perniciosus* in Europe (Feliciangeli, 2004). Some species are associated to specialized niches, like termite hills in Kenia (*Ph. celiae*) and caves and among rocks in East Africa (*Ph. longipes* and *Ph. pedifer*) (El-naïem, 2011).

Larvae of four instars feed on organic matter on the soil and molt to pupae, with an egg-adult cycle of about 40 days. Localization of immature forms is very difficult, due to low knowledge or to their scattered distribution, and productivity of searches is usually small. Sixty-one larvae and 91 pupae were collected in Sebastopol, in former Soviet Union, after processing six tons of soil, in 965 samples, and in the Brazilian state of Paraná, in a locality where more than 200,000 insects could be collected per year, 0.8 insects/m² (total – 21 insects), and six from emergence traps were obtained (Reinhold-Castro et al., 2015), illustrating the difficulty of such search. In a rare example of success, more than 1500 immature forms were collected inside an abandoned cement building in Sardinia (Bettini et al., 1986).

Male adults have an 180° rotation of external genitalia in the first 24 h, and the collection of non-rotated males indicates the probable proximity of locality of collection to breeding places. Both sexes feed on carbohydrates from vegetal sap and secretions of aphids. Ingestion of sugars is fundamental for flight and other activities, and very important for development of *Leishmania* in the digestive tract of females. Louradour et al. (2017) indicated the importance of microbiota in the midgut of *Ph. duboscqui* on the development of *L. major*, emphasizing the role of glucose on the osmotic conditions for the survival of infective promastigotes.

Females also feed on blood by laceration of skin and capillaries, due to their short proboscis (0.2–0.4 mm), being pool-feeders (or telmophages) (Lavoipierre, 1965). Saliva is very important for preventing hemostasis. As an incidental result, saliva also influences the development and transmission of *Leishmania*, and intensive studies have been developed on their constitution and function, with possible usefulness for development of tests and vaccines. For example, it has been suggested that Costa Rican *Lu. longipalpis* containing little maxadilan, a potent erythema-inducing peptide, promotes cutaneous proliferation, while those from Brazil, richer on this peptide, promote visceralization (Warburg et al., 1994).

For most species, it is assumed a gonotrophic concordance, with some exceptions. So, it is possible to evaluate the quantity of blood meals from the analysis of internal structures related to egg-laying. Small size of insects makes difficult this task.

However, autogeny has been observed in some Old and New World species: *Ph. papatasi*, *Lu. gomezi*, *Lu. cruciata* and possibly *Psychodopygus davisi* and *Pintomyia damascenoi* (Forattini, 1973). In the laboratory, *Pi. mamedei* is autogenous and parthenogenetic, just producing females (Brazil and Oliveira, 1999). *Deanemyia maruaga* (Alves et al., 2011a), whose larvae have a visible reserve of fat in the abdomen, unusual in such flies and attributable to richness of guano in the cave they live, also is apparently autogenous and parthenogenetic (Alves et al., 2011b).

Blood feeding is mostly nocturnal, but some species may feed during the day, mostly in shaded areas in caves and forest areas. *Nyssomyia umbratilis*, when disturbed on tree trunks, may bite during the day, sometimes causing multiple lesions by *Leishmania guyanensis*. Most species are eclectic and opportunistic in their feeding choices, and may present different preferences according to region, as observed for *Ny. whitmani*. *Psychodopygus wellcomei*, an important vector of *L. braziliensis* in the Amazon forest, also bites during the day, and *Ps. complexus*, a very similar species and a vector in some areas, bites mostly between 6 and 8 a.m. (Godoy et al., 2016).

They usually disperse for short distances, but *Lutzomyia longipalpis* and some other New World species associated to human modified environments and several Old World *Phlebotomus* seem to disperse for some hundreds of meters. In a coffee plantation at Colombia, flights of up to 100 m for *Psathyromyia shannoni* were observed, but marked flies of *Pi. spinicrassa*, a much more plentiful species in the area, were rarely recaptured (Alexander, 1987). Another study in similar environment showed dispersion of *Pa. shannoni* to 200 m, and a female of *Lu. gomezi* was found at 960 m from the point of release (Alexander and Young, 1992). Ready et al. (1986) noticed continuous flights of sand flies of several species for at least 20 m in the first 5 minutes after releasing, and J. D. Andrade (pers. commun.) collected sand flies in a boat at 80 m from the edge of a river in the Brazilian state of Minas Gerais, showing the possibility of long flights without landing.

Influence of wind on sand flies has been studied for some species, and results are variable. Wind speeds between 1 m/s (=3.6 km/h) and 4 m/s (=14.4 km/h) were considered as prejudicial, and >4 m/s as prohibitive (Lane, 1993), but this seems to be variable according to interaction to other factors, as shown by a study in Saudi Arabia (Roberts, 1994). Since they have a predominantly hopping flight, it is necessary to check if wind can transport them to large distances, like biting midges.

A difference between the movement of *Ph. argentipes* and *Sergentomyia* sp. to the palm tree canopy in Bihar (India) was noticed. One-hundred and four from 105 flies collected by sticky traps around the trunk were *Sergentomyia*, but *Ph. argentipes* was the only species on CDC traps (130 flies in 29 trap days) in the canopy, an indication of direct flights (Poché et al., 2012).

Males arrive in the vicinity of host animals before females; they compete with each other for females in lekking displays (Bray and Hamilton, 2007) where their hopping and wing fanning are believed to distribute pheromones that encourage female choice (Jones and Hamilton, 1998). Males spend longer on and around hosts than the more discrete females, and this may contribute to the higher male: female ratio (typically >3:1) caught in both CDC mini light traps and pheromone traps in the proximity of breeding sites.

Ecology

Most species are associated to habitats not modified by human activity, but several species are adaptable to modified environments. There is a gradient of adaptation to different environments. For example, in the New World, *Psychodopygus* spp. are well adapted to forest, becoming very rare after deforestation. They are replaced by species of *Nyssomyia*, like *Ny. whitmani*, and those of *Ny. intermedia* complex (*Ny. intermedia* and *Ny. neivai*), and very modified places may be populated by *Lutzomyia longipalpis*. The last four species may invade houses and annexes. Deforestation around henhouses and utilization of insecticides on them in the Brazilian state of Paraná caused the replacement of *Migonemyia migonei* by *Ny. whitmani* as the predominant species (Teodoro et al., 1999).

Type of soil may influence predominance of species. For example, in the Brazilian state of Paraná, *Ny. neivai* is predominant in areas with sandier soils, while *Ny. whitmani* is more frequent in areas with red and red-yellow latosol or nitosol soils (Teodoro et al., 2006).

In desert areas in Iran (Yaghoobi-Ershadi, 2012) and the South of former USSR, *Ph. papatasi*, a vector of *L. major*, is associated to burrows of great gerbils, good reservoirs of the parasite. In Tunisia, they have a strong association to rabbit burrows (Chelbi et al., 2008).

Medical and veterinary importance

Damage by biting

Bites of sand flies can cause skin irritation and have been compared to the touch of a red hot pin. They are referred as *quemador* and *pringador* in some areas of Colombia, referring to this sensation. The hypersensitivity reaction to bites of *Ph. papatasi* is called *harara*

in Palestine, and the Author observed a measles-like skin in some children frequently bitten by *Lu. longipalpis* in the East of Brazilian state of Paraíba.

Pemphigus foliaceus is an autoimmune disease present in several South American countries, and also in Tunisia, called *Fogo Selvagem* (FS, wild fire) in Brazil. It is characterized by skin blisters and exfoliation, and can assume several forms and become very serious (Aoki et al., 2015). It has been associated with bites of sand flies and black flies (Vernal et al., 2017), and *Lu. longipalpis* salivary antigens can initiate a cross-reactive IgG4 response in genetically susceptible individuals, leading to FS (Ye et al., 2012).

Transmission of pathogenic agents

Leishmaniasis is usually divided in visceral and cutaneous forms, according to predominant localization of parasites. However, the localization and evolution of disease is influenced by several factors, like the species and strain of parasite, the immunity, and even the sand fly injecting it in the host. Visceral leishmaniasis (VL) can be mortal, mostly when associated to malnutrition or AIDS, and cutaneous leishmaniasis (CL) can cause serious deformities, mostly when affecting mucosae or disseminating in the body.

In 2016, VL caused 707.9 Disability-Adjusted Life Years (DALY) and CL 273.1 DALY, with a reduction of 70.6% in VL and an increase of 117.9% in CL from 1990 incidence in the world (Hay et al., 2017).

Leishmania has been divided in four subgenera: *Leishmania*, *Viannia*, *Mundinia* and *Sauroleishmania* (Espinosa et al., 2018). The last subgenus occurs in lizards, and parasites, only present in the hindgut of flies, need to be ingested by the vertebrate host. Subgenus *Leishmania* is usually restricted to midgut of flies, and *Viannia* also has parasites in the hindgut, and in both subgenera, they need to migrate to proboscis to be transmitted. *Mundinia* includes some badly known parasites of *L. enrietti* clade from South and Central America, Southeast Asia and Australia. Some *Leishmania* (*Mundinia*) of horses in Europe (Müller et al., 2009) need to be more carefully studied.

Leishmania of the first two subgenera, with 16 species already reported in humans (Ready, 2013) are vectored by sand flies, from more than 30 known species. Sand flies acquire amastigote forms, usually contained in macrophages, when blood feeding on mammals. In their guts, they suffer a series of modifications, finally producing metacyclic promastigotes (Kamhawi, 2006), which may be injected in the following bites.

Leishmania (*Mundinia*) *siamensis*, causing infection in humans in Thailand, is a *nomem nudum* and a synonym of *L. martiniquensis* (Espinosa et al., 2018), and in Australia, biting midges have been incriminated as vectors of *Leishmania* (*Mundinia*). A review of this group is mandatory.

Although flies of many species have been found infected by *Leishmania*, no more than 70 species have been implicated in transmission. The actual role of a species of sand fly as vector is determined by seven conditions (Ready, 2013), the last two added to five previously proposed by Killick-Kendrick (1990): (1) on more than an occasion, promastigotes were isolated or typed from wild females not containing blood meals; (2) many forms of *Leishmania* are found in the anterior midgut or stomodeal valve; (3) flies are attracted to and bite humans and reservoir hosts; (4) strong ecological association, including seasonality, is shown between fly, humans and reservoir hosts; (5) experimental transmission is achieved after infection from a natural host or laboratory model. Mathematical modeling demonstrates: (6) that the vector is essential for maintenance of infection with or without the involvement of other vectors and (7) that a significant decrease in the incidence of disease following a significant decrease in the biting density of the specific vector.

Incriminated and suspected vectors of all species of *Leishmania*, respectively meeting criteria 1–4 and only some of them, were listed, but no fly satisfied criteria 6 and 7 yet, and in reality, none is actually a proven vector (Ready, 2013). Maybe the implantation of evidence-based control (Wilson et al., 2015) could obtain better results, besides defining the role of each species in the transmission.

Some vectors (*Ph. papatasi*, *Ph. sergenti*) support the development of only their specific parasites, while *Lu. longipalpis* is susceptible to several parasites. *Leishmania*-host adaptation may be influenced by several factors, including the parasite lipophosphoglican (LPGs) (Kamhawi et al., 2000) and proteophosphoglicans (PPGs) (Secundino et al., 2010), respectively responsible for mediation of midgut binding and for prevention of digestion by midgut enzymes. Galectins, associated to LPGs, also have a function on binding to midgut surface and could be targeted in vaccines (Kamhawi et al., 2004). Some parasites have been shown to secrete a promastigote secretory gel (PSG), with filamentous PPGs, in the anterior midgut, which enhances transmission of *L. infantum* and *L. mexicana* by *Lu. longipalpis* (Rogers and Bates, 2007; Ready and Rogers, 2012).

This does not mean that no other species will be incriminated in the future, mostly due to ecological modifications, like deforestation and global warming. For example, in a study at Peruvian Amazonia, sand flies of 14 species in several genera were found infected by *L. braziliensis*, *L. guyanensis* or *Leishmania* sp. (Zorrilla et al., 2017), and infection of *Warileya rotundipennis* by *Leishmania* (*Viannia*) was reported in Colombia (Moreno et al., 2015).

Epidemiology of leishmaniasis is influenced by several factors, including ecology of vectors, reservoir hosts and species and strains involved. It is extremely diversified according to species of parasite and region, with some examples below.

The influence of several factors on the epidemiology of leishmaniasis must be carefully studied. A comparison between different areas (natural, urbanized, with or without some vegetation or reservoir etc.) is essential for understanding the transmission.

In Palestine, five transects were set between a rocky area with hyrax reservoirs of *L. tropica* and that containing houses (Salah et al., 2020). The risk of transmission to humans by *Ph. sergenti* increased with higher density and closer proximity to reservoir hosts and higher densities of vector near houses.

Leishmania guyanensis, widely distributed in the East of Andes, is associated to tree trunks at North of Brazil. *Nyssomyia umbratilis* bites sloths and anteaters in the canopy, becoming infected, and after going to the soil to oviposit, may bite people near the trunks; there are several other suspected vectors (Ready, 2013).⁴ *Leishmania braziliensis* has a wide distribution from Belize to Argentina, with several vectors and reservoir hosts, transmission being done in several environments, varying from primary forests to houses.

Leishmania major is transmitted in Sahel dry savannas in Sub-Saharan Africa and Yemen by *Phlebotomus duboscqui*, with rodents as reservoir hosts, while *Ph. papatasi* is its vector, with gerbils and other rodents as reservoir hosts in areas of North Africa, Middle East and South of Asia (Ready, 2013).

Leishmania infantum is mostly transmitted by *Ph. ariasi*, *Ph. perniciosus* and other species of *Phlebotomus* (Larroussius) and by *Ph. chinensis* in Eurasian areas, and mostly by *Lu. longipalpis* in Neotropical region. It has been reported in areas at southern and center-western Brazilian states, without the presence of *Lu. longipalpis*, and alternative vectors have been proposed for the above regions. Dogs and humans are reservoirs, and some wild dogs and possibly opossums are sylvatic reservoirs of the parasite.

Leishmania donovani, causing VL and PKDL (Post Kala-azar Dermal Leishmaniasis), is transmitted by *Ph. argentipes* in the Indian subcontinent and by *Ph. orientalis* and *Ph. martini* in East Africa; humans are the only reservoirs, except in some African savanna areas (Ready, 2013).

As an example of diversity of epidemiology of leishmaniasis, in China *L. infantum*⁵ has different vectors, reservoirs and life cycles in different regions of the country. It can cause CL in a small focus of Karamay, VL in anthroponotic cycle (AVL) in Kashi in the north-west (Xinjiang) and zoonotic cycle (Mountain Type – MT-ZVL) in mountainous areas in the western provinces of Sichuan and Gansu, with dogs as reservoirs, and in oases in the north-west (Desert Type – DT-ZCL), with *Ph. wui* as the vector. For AVL, no reservoir besides humans has been found, and vectors are *Ph. chinensis* in most places and, in Xinjiang, *Ph. longiductus*. For MT-ZVL, dogs are frequently infected and *Ph. chinensis* is the vector, while for DT-ZVL several vectors and a species of hare (*Lepus yarkandensis*) has been found infected (Lun et al., 2015). Ecology and distribution of four (three above plus *Ph. alexandri*) major vectors of VL in China was recently reviewed (Guan et al., 2016).

Human behavior is very important for infection. In sylvatic areas, men are usually more exposed to infection by *Leishmania* spp., due to their activity, than women and children, unless these also frequent those areas. On the contrary, if transmission is in or near the house, the chance of infection is similar for both sexes, if transmission is effected at night, but more women will become infected if this transmission is during the daytime, when men are probably out. So, the epidemiological investigation must include a careful survey of human activities.

In some areas of French Guiana, risk of transmission of *Leishmania* (probably *L. guyanensis*) to humans is higher in the short time between two rainy seasons, in the first half of November, when the quantity of infected *Ny. umbratilis* is greater (Le Pont and Pajot, 1980).

Flies that have already fed on blood and laid eggs (parous), which may be infective, may bite in different hours of the day, compared to those that have not yet produced eggs, and so have not blood fed (nulliparous). For example, a significantly greater proportion of parous females of *Psychodopygus wellcomei* bite in the morning than in the evening, indicating a higher risk of infection in that time (Wilkes et al., 1984).

Since some areas of Amazonia may have more than 60 species of sand flies (e.g., Galardo et al., 2015) and sometimes several species of *Leishmania*, the epidemiological study may be very laborious.

Environmental modifications through the building of dams for electricity (Galardo et al., 2015) or global warming (Moo-Llanes et al., 2013) may influence the predominance of fly species and their role in transmission of *Leishmania*.

Trypanosomatids of *Endotrypanum* (*E. schaudinni* and *E. monterogeii*), also are transmitted by sand flies, with sloths as vertebrate hosts. These protozoa are phylogenetically near *Porcisia hertigi* and *P. deanei*, from porcupines, also transmitted by sand flies (Espinosa et al., 2018).

Bartonellosis, caused by *B. bacilliformis*, one of 17 species in the genus, occurs in Andean valleys in Peru, Ecuador and Colombia, with possibility of cases in Brazil and Bolivia, due to its occurrence also in the Amazonian region. *Pintomyia verrucarum* and *Lu. peruensis* are usually the major vectors, but *Pi. maranonensis* and *Pi. robusta* were also found infected, among several suspected vectors (Garcia-Quintanilla et al., 2019).

This is a neglected disease, mostly in isolated (and poor) small villages, and more studies must be developed. *Lutzomyia peruensis* and *Pintomyia verrucarum* are considered as primary vectors, and *Pi. maranonensis* has been recently found infected in Peru (Ulloa et al., 2018). Natural infection of ticks and experimental transmission has been demonstrated, but their role has also been considered doubtful (Telford III and Wormser, 2010). A *Bartonella* sp. near *B. grabhami* and *B. elizabethae*, emerging pathogens that can cause endocarditis in dogs and humans, was isolated from 8.69% of sand flies (2/26) in Mexico (Lozano-Sardaneta et al., 2019).

Several *arboviruses* are transmitted by sand flies. They belong to Rhabdoviridae (mostly *Vesiculovirus* – VSV group), Bunyaviridae (*Phlebovirus*) and Rheoviridae (*Orbivirus*). Some of them may cause febrile diseases, meningitis and even death.

⁴In a short visit to a forest in Recife, in the northeast of Brazil, Bruce Alexander collected some *Ny umbratilis*, the predominant species (96%) in the area, on a tree trunk (Balbino et al., 2001).

⁵Although Lun et al. (2015) called all protozoa *L. infantum*, *Leishmania donovani/infantum* complex is very diversified in China, sometimes with several different strains in the same locality (e.g., Xinjiang) (Alam et al., 2014), and even including some undescribed *L. (Sauroleishmania)* (Yang et al., 2013).

Vesiculovirus includes several human and veterinary pathogens as Chandipura (CHAV), in India, and Vesicular Stomatitis Indiana (VSIV) and Vesicular Stomatitis New Jersey (VSNEJV), in the New World. Ten of them have been associated to sand flies (Comer and Tesh, 1991).

Infection of salivary glands of *Ph. argentipes* (Mavale et al., 2007) and venereal transmission by *Ph. papatasi* of Chandipura virus were obtained. In the American continent, VSNEJV may be experimentally transmitted by sand flies, biting midges and horse flies, but transovarial transmission has been demonstrated only in sand flies (Rozo-Lopez et al., 2018).

Phlebovirus is one of five genera in Bunyaviridae, and includes 70 species, classified into two broad groups: the sandfly (or phlebotomus) fever group, which includes Rift Valley virus, mostly transmitted by mosquitoes, and Toscana viruses, with sand flies as vectors, and Uukuniemi group, with three species transmitted by ticks, besides some newly described mosquito-specific viruses (Palacios et al., 2015). Toscana viruses, usually isolated from *Ph. perniciosus* and *Ph. perfiliewi*, have wide distribution in Central and Eastern Europe, North Africa and Turkey, probably transmitted by several species of sand flies (Aihan et al., 2020).

Orbivirus has been found only in tropical New World, mostly in the Amazon region, where 52 arboviruses of Changuinola antigenic group were isolated from sand flies between 1961 and 1995 (Shaw et al., 2018).

Transovarial transmission of arbovirus seems to be frequent in several species of sand flies, but at variable rates. This probably compensates short parasitemia of several of these arboviruses (Tesh and Chaniotis, 1975).

Sand flies have been found infected by several species of Trypanosomatidae from Amphibia, Reptilia and Mammalia, and the study of infection and interaction between several of these parasites in sand flies must be developed (Shaw et al., 2018). *Plasmodium* of reptiles also are transmitted by sand flies, with more than 50 known species (Ayala, 1978), and may influence biology and competition of animals (Bower et al., 2018).

Methods for sampling, rearing and research activity

Detection of adults

Sand flies may be collected when trying to bite humans and domestic animals. Baits need to be protected to prevent the risk of infection. Traps have been designed to collect these flies.

Adult flies may be sucked by mouth-aspirated tubes, with adequate filters to prevent suction of setae, scales and mold. On walls, light from flashlights must preferably be projected in parallel to surface. According to future processing, they may be blown on in 70° GL ethanol or in a small plastic cage (Marcondes et al., 2007) or other cage types (Lawyer et al., 2017), utilizing voile instead of screen.

Taking advantage of the hopping flight of flies, a trap with a metal tray, supporting a small cage with an animal and having a layer of Castor oil was produced (Disney, 1966), being improved by Dorval et al. (2007), mostly adding a protection from predation, stealing and rain. This trap is very productive for rodent-attracted flies, like *Bichromomyia flaviscutellata* and *Ny. olmeca*, respectively vectors of *L. amazonensis* and *L. mexicana*, but also collected other 10 species, including *Lu. longipalpis* (Dorval et al., 2007).

Miniature light traps have been very useful to collect sand flies, preferably utilizing LED (Silva et al., 2016). Shannon trap, composed by a 3 × 2 × 2 m box of cloth with eaves, preferably utilizing a lampoon with batteries,⁶ fed by photoelectric cells, to attract insects, is very useful (Figs. 5 and 6). Since composition of samples is different with black or white cloth (Brilhante et al., 2017), both types should be used. Due to limitations on the utilization of light traps to evaluate the risk of transmission of pathogens, other methods should be utilized in parallel.

The method of collection is very important for the composition of samples. Several methods must be utilized in the same area, for a more complete knowledge of the fauna, and results from different types of traps cannot be statistically compared. Sampling endophagic species in the Peruvian Andes, the proportion of *Pi. verrucarum* was higher in light trap than in human bait catches, an indication that *Lu. peruensis* is more anthropophilic or less phototropic than *Pi. verrucarum* (Davies et al., 1995). Methods for collecting and processing sand flies were recently reviewed (Alten et al., 2015; Vilela et al., 2018).

Observation of meteorological conditions during the collections is fundamental for the evaluation of biology and ecology of sand flies (Fig. 6).

The identification of blood feeding source is very important, and precipitin, ELISA and Real-Time PCR techniques have been utilized for the identification. The last, for its sensitivity (10 pg to 100 fg) and specificity (Sales et al., 2015) should be chosen if adequate material and equipment are available.

Detection of immature forms

Land may be examined or processed with NaCl or sugar solutions to get the immature forms. The first substance is noxious for the forms and the second may attract house flies, mostly if utilized in open environments (L. M. Deane, 1974 - pers. commun.).

⁶Utilization of electric generators is cumbersome, and gas or kerosene lampoons are too dangerous, I remember to have carried in the beginning of 1974 a heavy Honda generator on the mountains of the primary forest in the southeast of the Brazilian state of São Paulo, and some of our Shannon traps were damaged by contact to lampoons.

Fig. 5 Shannon trap.

Fig. 6 Bench to wait for sundown for the collection by Shannon trap (ST), to collect with human bait and to sustain light source, with a thermo-hygro-anemometer, a GPS and a light source with photoelectric charge. The box (or a back pack) is utilized to transport the ST.

Immature forms may be localized by the utilization of funnels or similar structures on the soil to collect the adults emerging from it, like that of [Casanova et al. \(2013\)](#), derived from the one described by [Ferro et al. \(1997\)](#).

[Casanova et al. \(2013\)](#) obtained good results for the collection of *Lu. longipalpis* (119 of 131 flies) and other sand flies with a soil emergence trap utilizing PVC tubes, with adhesive tape in the inner surface of superior part, covered by voile ([Fig. 7](#)). They collected 57 flies/m² in chicken sheds, with an estimative of production of 121 flies/m² per day.

A detailed study on habitats in Amazon forest, utilizing three techniques (floatation-sieving, Berlese–Tullgren funnels, and direct examination), examined 370 l of material, of which positive samples constituted 59 l. One-hundred eighteen sand flies of 18 species were obtained, mostly from tree bases ([Alencar et al., 2011](#)).

Fig. 7 Emergence trap for sand flies. (A) Fixing the trap to the ground; the serrated bottom facilitates its fixation in the soil. (B) Placing the adhesive paper. (C) Covering the trap with a sand fly-proof fine mesh to prevent sand flies escaping. (D) Traps covered with a small tent. Courtesy of Cláudio Casanova. From Casanova C, Andrighetti MTM, Sampaio SMP, et al. (2013) Larval breeding sites of *Lutzomyia longipalpis* (Diptera: Psychodidae) in visceral leishmaniasis endemic urban areas in southeastern Brazil. *PLoS Neglected Tropical Diseases* 7: e2443.

Proteins specific for immature forms of four laboratory-bred species of sand flies were detected by matrix-assisted laser desorption/ionization time of light mass spectrometry (MALDI-TOF MS), much more efficiently than for biting midges (Halada et al., 2018). By Real Time-PCR, the presence of 1 larva/40 ml of soil could successfully be detected (Giantsis and Chaskopoulou, 2019).

Natural infection

Dissection of flies for the finding of infection, isolating and studying the parasites, has been widely utilized. Briefly, head is cut in saline, and the posterior tip of abdomen is partially separated and pulled in zigzag movement, examining under microscope with a coverslip. Positive material may be inoculated in hamsters and/or cultivated in adequate media. Localization of parasites in the gut can be checked, but there is risk of contamination and loss of samples, and the analysis of thousands of flies is very tiring.

Molecular methods have been utilized. The head and the last two abdominal segments of each fly are dissected for identification, and the rest is processed by several techniques. Material must be preserved at -20°C or in absolute ethanol, and slides and pins utilized for dissection must be washed in potassium hydroxide between flies. After identification of flies, they may be grouped in pools of the same species and origin. If available, techniques for molecular simultaneous identification of flies may be utilized.

A DNA sequencing based multi detection test for the detection and identification of *Leishmania*, blood sources, plant meals and intestinal microbiome was developed (Abbasi et al., 2019).

Tests to evaluate the presence of metacyclics and of other forms of *Leishmania* in sand flies have been recently developed (Giraud et al., 2019; Coutinho-Abreu et al., 2020) and are very useful for the evaluation of their role as vectors. More research to get a marker of gene expression exclusive for these forms is necessary.

Laboratory rearing

For starting colonies, fed females must be put in vials or cloth cages, maintained in dark and very wet environments. Adults are fed on several animals, like mice and hamsters, and even utilizing artificial membranes, according to species and experience of laboratories; chicken may be utilized, but they are rather messy. In the beginning of colonies, flies can refuse to feed on anesthetized rodents, and nude guinea pigs may be utilized. Sugar in cotton balls must be furnished and daily replaced.

A Petri dish with a layer of plaster of Paris must be exposed and saturated by placing the pots in a tray with water 5 days after blood feeding of females, immediately stimulating egg-laying. Dead and living insects must be removed with a vacuum-powered pipette after egg-laying, reducing the chance of larvae eating dead adults and getting infection by gregarines and other pathogens. Eggs must be removed and washed in a 1% sodium hypochlorite solution, rinsed with tap water and placed back into oviposition/rearing pots.

Larvae are fed by a 1:1 mixture of rabbit chow and rabbit feces, preventing proliferation of fungi. These and other techniques, including “tricks” to rear some species, like *Pi. youngi*, are extensively described by [Lawyer et al. \(2017\)](#), which must be consulted.

Although colonies are very important, mostly for insecticide susceptibility tests and studies of biology and experimental infection, this activity is very time-consuming, and there is a high risk of contamination and loss of colonies, probably a factor for so few species having been mass reared.

Control

Factors to help control of leishmaniosis and to worsen it were respectively called *yang* (=clarity: access to funds, collaboration, commitment, effective vaccines, rapid case detection, diagnosis and treatment) and *yin* (darkness: conflict, drug and insecticide resistance, global warming, new parasites/vectors/reservoirs, unknown or inaccessible reservoirs) ([Kamhawi, 2017](#)).

[Alexander and Maroli \(2003\)](#) reviewed several types of transmission, defining vectors, hosts and effect of seasonal variation and human behavior. Methods for the control of leishmaniasis through the control of vectors and reservoirs were recently reviewed ([González et al., 2015](#)).

For the control of sand flies and transmission of *Leishmania* and other pathogenic agents, it is necessary a deep knowledge of the epidemiological situation and biology of vectors and reservoirs, and non-effective interventions that reduce transmission but not eliminate it may worsen the situation due to reduction of bites and immunization by the flies' saliva ([Courtenay et al., 2017](#)). Although several methods have been utilized for the prevention of transmission of *Leishmania*, 35% have not included human-specific outcomes and are difficult to generalize to different geographic locations, being advisable to know more on the epidemiology ([Stockdale and Newton, 2014](#)).

For example, if the cycle is partially or totally anthroponotic, treatment and personal protection, associated to control of vectors, will probably be effective, but if it is zoonotic, the destruction or isolation of reservoirs or breeding sites (e.g. rodent burrows) is useful. If transmission is in or around houses, several methods cited below would be effective, but since no sand fly is exclusively adapted to houses, it is not possible to eradicate any of them, and protection will be effective only when maintained.

Since Carrion's disease has a restricted geographical distribution, lacks non-human reservoirs and may be cured by antibiotics, it is a potentially eradicable disease. However, the invisibility of this disease of very poor populations in isolated rural areas of South America is the Achilles heel of commitment to eradication ([Gomes and Ruiz, 2018](#)).

Insecticides

Adults

For sand flies adapted to domiciles and annexes, the application of several insecticides has produced good results in some conditions. However, the efficacy has been affected by the existence of populations of the same species out of those environments, resistance to insecticides and low knowledge of their biology.

The utilization of DDT, associated to treatment of patients produced a reduction of incidence of VL in the Indian subcontinent. Because of application of DDT for the control of malaria in India, in 1958–1970, no case of VL were reported on Bihar during this period ([Alexander and Maroli, 2003](#)). However, the surging of cases in other areas, difficulty of treatment with new and efficient drug milfetosine ([Selvapandiyan et al., 2019](#)), and symptomatic PKDL (Post Kala-azar Dermal Leishmaniasis) and HIV co-infected patients complicate the control ([Singh et al., 2016](#)). Although pyrethroids have shown to be efficient in the control of the vector *Ph. argentipes*, the persistence of outdoor populations, associated to sleeping outside in part of the year complicates control ([Singh et al., 2016](#)).

DDT was also successfully utilized to control the transmission of *Leishmania* in several countries, also simultaneously controlling bartonellosis in Peru, since the 1940s. Lambda-cyhalothrin also was efficient to control *Pi. verrucarum*, vector of *L. peruviana* and *B. bacilliformis* ([Davies et al., 2000](#)).

Resistance to insecticides has been reported in the Indian subcontinent for *Ph. argentipes*, *Ph. papatasi* and *Sergentomyia shortii*, and some tolerance have been observed ([Alexander and Maroli, 2003](#)).

Deltamethrin and other synthetic pyrethroids have shown some effect on *Lu. longipalpis*, as observed in a test in Bolivia ([Le Pont et al., 1989](#)); it was not effective for *Pi. nuneztovari anglesi*, probably due to its more exophilic behavior. However, a test has indicated

the presence of adults of *Lu. longipalpis* hopping on walls pulverized 2–3 weeks before (Marcondes and Nascimento, 1993), and R. P. Brazil (2009 – pers. commun.) cited the finding of living flies on a surface pulverized 1 week before.

Susceptibility of *Lu. longipalpis* to alpha-cypermethrin varied according to locality in the Brazilian state of Minas Gerais, from susceptibility in a population from a cave (Lapinha) to variable resistance in other localities.

Due to small size of sand flies, non-impregnated bed nets may be useless for protection against bites, but *impregnated bed nets* and *impregnated curtains* are useful for the control of VL and CL (Alexander and Maroli, 2003).

Nyssomyia ovallesi and other species in Venezuela passed through a 6-mm mesh net treated by deltamethrin at 15 mg/m² and could bite volunteers (Felicangeli et al., 1995). Alexander et al. (1995) observed a significant reduction of bites of *Lu. lichyi* and the predominant *Pi. youngi*, under treated nets (64 holes/cm² = 412 holes/in²), and impregnated curtains significantly influenced collections of both species and also of them plus *Pi. columbiana*.

Bed nets impregnated by deltamethrin reduced transmission of *L. major* and *L. tropica* in Iran, while non-impregnated ones did not provide any protection (Yaghoobi-Ershadi et al., 2005; Moosa-Kazemi et al., 2007). In Turkey, Olyset® Plus nets incorporated with 2% permethrin and 1% pyperonyl butoxide (PBO, a synergist) reduced incidence of CL caused by a hybrid *L. infantum/L. donovani*, with *Ph. tobbi* as a proven vector, by 92.2%, and the nets retained full insecticide strength for 12 months (Gunay et al., 2014).

Tests of Permanet® bed nets acquired impregnated by deltamethrin (Long Lasting Insecticidal Nets – LLIN) with three mesh sizes (196 mesh/in. with and without a sand fly-proof 75 cm border and 156 mesh/in.) indicated absence of statistical difference between them; the last was preferred, due to the and smaller reduction on ventilation (Singh and Kumar, 2016).

For *Ph. argentipes*, reducing the size of holes from 156 holes/in² to 625 holes/in² (1 in² = 6.4516 cm²) of non-impregnated nets increased the barrier effect by 60% (56–88%), while impregnating 156 holes/in² nets by alpha-cypermethrin (200 mg/m²) reduced the number of flies under the net by 77% (27–93%) (Das et al., 2014).

Impregnated curtains (permethrin at 50 g/m²) were tested in henhouses in Argentina, reducing the density of *Ny. whitmani* (Acosta et al., 2017), with potential use for the control of *Lu. longipalpis*, which is very attracted by chickens (Alexander et al., 2002). The utilization of curtains impregnated by permethrin (0.5, 1.0 and 1.5 g/m²) in rooms significantly reduced the density of *Ph. papatasi* in Sudan (El-naïem et al., 1999).

Cotton wall cloths impregnated with 0.5 mg/m² permethrin inside houses retained insecticidal effect for 6 months against *Ph. martini* and *Ph. dubosqui* in Kenya, reducing the quantities collected in houses by 76 and 85%, respectively (Mutinga et al., 1992, 1993). These curtains and bednets have been useful for the control of VL by *L. donovani* in East Africa, mostly transmitted by *Ph. orientalis* (El-naïem, 2011).

In visceral leishmaniasis caused by *L. infantum*, mostly in Brazil, it was recommended in the 1950s the association of DDT pulverization in houses and annexes, killing of positive and suspect dogs and treatment of humans. However, positive dogs, which were difficult to find, spend a time infecting flies before being eliminated and were rapidly replaced by young (and susceptible) ones, besides the resistance of owners and associations for protection of animals and ethical problems (Dantas-Torres et al., 2019). The failure of pyrethroids to control *Lu. longipalpis* and the difficulties on diagnosis and elimination of infective dogs stimulated the audacious proposal of reevaluate DDT for the control of VL in Brazil (Marcondes and Costa, 2014).

Collars impregnated by insecticides, direct application and *vaccines* have been successfully tested to prevent infection of dogs, which would not become reservoirs of parasite.

Since Killick-Kendrick et al. (1997) first demonstrated collars impregnated by deltamethrin had a potent antifeeding effect on *Ph. perniciosus* and killed 60% of the insects, many successful tests of these collars were developed. Collars impregnated by 4% deltamethrin (Albuquerque e Silva et al., 2018; Kazimoto et al., 2018) or 10% Imidacloprid/4.5% Flumethrin (Otranto et al., 2013) have been utilized for protection of dogs against infection by *L. infantum* and the control of visceral leishmaniasis, and the last also got a 75% protection of felines (Brianti et al., 2017).

Pyrethroids applied in shampoos have also been utilized for protection of dogs and cats against several biting arthropods, but they need frequent reapplications (Otranto and Wall, 2008). Flumethrin applied *pour on* to dogs was effective to reduce biting by sand flies (no specified species), inhibiting biting and killing 90–100% of exposed flies until 2 months after application (Jalilnavaz et al., 2016). Imidacloprid plus permethrin (Advantix®) applied *pour on* in dogs protect against bites of *Ph. perniciosus* for at least 4 weeks (Bouhsira et al., 2018).

In conclusion, impregnated bed nets and curtains have been shown to be useful in the control of several forms of leishmaniasis, and the association to protection of dogs against bites, where they are reservoirs, may get a good control.

Repellents and clothes. Substances which can be applied on potential sources of blood and cause a reduction on the quantity of bites could be very useful for the control of sand flies and diseases. Several repellents have been shown to be efficacious against their bites. DEET, the less toxic Icaridin and several other substances, also useful for mosquitoes, are efficient to repel sand flies (Islam et al., 2017; Tavares et al., 2018). The above impregnated collars and insecticides exert a role on repellency of sand flies, being recommended for the protection of reservoirs of leishmaniasis (Dantas-Torres et al., 2019).

Sand flies are telmophages, needing to have direct contact to skin, unlike solenophages insects like mosquitoes and triatomine bugs. They will only bite exposed parts of the body, possibly insinuating into sleeves and collars.

Resting sand flies. Chanotis et al. (1982) treated the forest in Panama by a ULV mist of Malathion or tree trunks until the height of 1 m, reporting a reduction on quantities of flies in the second treatment, without defining the affected species.

Since *Ny. umbratilis* is associated to the bases of the larger forest trees and most contact between them and humans occurs when humans are near these trees, with possible infection by *L. guyanensis*, a trial was developed to control the insects in these places. DDT

was applied on the lower 4 m of all large trees (girth > 1 m) in the test area and, although there was a temporary reduction on quantities of flies on the treated trunks, no influence was noticed on collections by CDC traps (Ready et al., 1985).

Such methods obviously would be useful only in very special conditions, and care on pollution of forested areas would be mandatory.⁷

Control of infection by *L. major* in Iran by the control of sand flies utilizing insecticides in rodent (*Rhombomys opimus*) burrows has not been efficacious, but in some trials the elimination of rodents around houses has reduced transmission (Yaghoobi-Ershadi, 2016).

Wolbachia pipientis has been reported in some species of *Phlebotomus* (Benlarbi and Ready, 2003; Bordbar et al., 2014) and in lower proportions of *Lu. longipalpis* (Rocha et al., 2018), being a potential tool for the control of these insects and related diseases.

Immature forms

Insecticides

Since larvae and pupae of sand flies are very difficult to find, it has been difficult to apply methods of control for them.

Ivermectin at 2–100 ppm was added to food of hamsters, and larvae of *Ph. papatasi* eating feces of animals fed with all concentrations had significantly reduced survival, and all eating on feces of 20–60 ppm died (Mascari et al., 2008). The chitin synthesis inhibitors diflubenzuron (Mascari et al., 2007) and novaluron (Mascari and Foil, 2010) also impaired respectively the larva-pupa and larval molts. The insecticide fipronil killed all flies 28 days after ingestion by hamsters, also being efficacious against larvae (Mascari et al., 2013b). Baits with these and other toxic substances could be useful for the control of rodent-associated sand flies.

A study in a village at Bihar (North of India) showed that fipronil orally administered to cattle, affecting adults feeding on cattle and larvae feeding on their feces, would be successful to control *Ph. argentipes* and visceral leishmaniasis (Poché et al., 2016).

Due to the importance of *Ph. papatasi* as vector of *L. major* and the availability of several laboratory colonies (Lawyer et al., 2017), several tests like the above cited have been developed on this sand fly, but their effect on other important rodentophilic species, like *Bi. flaviscutellata* and *Ny. olmeca*, should also be developed.

Alternative methods

Environmental modification can be useful to control certain sand flies. In French Guiana, a village (Cacao) with *Ny. umbratilis* infected by *L. guyanensis* had a 11-ha area around it deforested, and insecticides were applied by fog in the village, causing a great reduction of incidence (Esterre et al., 1986).

The cleaning of the area around houses and henhouses, associated to the cutting of trees, reducing the shadow and drying the soil, associated to the utilization of insecticides in the houses and annexes, in the Brazilian state of Paraná reduced in 3.4 times the hourly means of collected sand flies (Teodoro et al., 2003). Due to the above cited association of *Ph. papatasi* to burrows of rabbits, not susceptible to infection by *L. major*, the promotion of their breeding near houses could be useful to control infection (Chelbi et al., 2008).

Feeding of sand flies of four species on *Cannabis sativa* in five regions was reported (Abbasi et al., 2018). Since the breeding of this plant is forbidden in most countries and it is certainly rare and hidden, this finding indicates a preference for it. They could even be utilized for localization of plantations, and the smell of the plants should be tested for attraction and killing of sand flies.

Ecological techniques for the association between adults and immature forms and for the control of rodent-associated sand flies, mostly utilizing isotopes, were studied by Mascari et al. (2013a).

Bacillus thuringiensis var. *israelensis* (Bti) added to sugar baits at concentrations of 4.4×10^2 – 10^4 killed 100% of *Ph. papatasi*, *Ph. argentipes* and *Lu. longipalpis* (Yuval and Warburg, 1989). Bti serotype 14 killed 100% of larvae of *Ph. perniciosus* after 6 days of exposition (Majori and Maroli, 1893). Also *B. sphaericus*, sprayed at the entrances of animal burrows in Kenya, or, diluted in sugar baits, onto the vegetation, caused great mortality to sand flies (Robert et al., 1997).

Attractive Toxic Sugar Baits (ATSB), when applied on vegetation and barrier fences in an arid region (Jordan Valley) caused respectively a reduction on samples to 6 and 12% of those in control areas (Müller and Schlein, 2011). In Morocco, ATSB caused a significant reduction on populations of *Ph. papatasi* and *Ph. sergenti* (Qualls et al., 2015). This method would be, like in other insects, promising for the control of sand flies, but should be tested in more rich and diversified environments, like tropical forests.

Some plants were shown to be toxic to *Ph. papatasi* (Schlein et al., 2001): *Solanum jasminoides* (Solanaceae), *Ricinus communis* (Euphorbiaceae) and *Bougainvillea glabra* (Capparaceae). The last is the most promising and could be cultivated around houses. More research is needed on this approach in other regions.

Different members of the *L. longipalpis* species complex in Brazil produce different sex/aggregation pheromones (Hamilton et al., 2005). Synthetic copies of these pheromones present potential as tools for survey and monitoring, if associated with insecticides. This lure-and-kill method can be used for their control and reduction in *Leishmania* transmission (Bray et al., 2010, 2014; Courtenay et al., 2019).

⁷In the 1980s, an undergraduate student of mine proposed in an examination to apply insecticides by plane on forests to control leishmaniasis, and in the 2000s a man from Florianópolis proposed the same on mangrove swamp, to control biting midges, not noxious because “the area was small.”

The kairomone lactic acid was useful for surveying sand flies in the Brazilian state of Maranhão, when associated to incandescent lamps, but not to diode lights, while octenol did not produce significant increases on quantities of flies collected (Silva et al., 2019).

Vaccination

This tool may be useful, mostly to protect humans and reservoirs from infection. Leishmanization has been utilized for several centuries in Middle East and from the beginning of 20th century also in former Soviet Union for the protection against cutaneous lesions caused by *Leishmania*. Exudate from a lesion was inoculated in a covered part of the body, to prevent lesions in the face. *Leishmania major* has been utilized, providing crossed protection against *L. tropica* (Mohebbi et al., 2019). Promastigotes from *L. tropica* were inoculated from 1910 on, just after the production of NNN medium in 1908. Although leishmanization has been shown as useful for the protection against infection, a selection of less pathogenic strains would be fundamental.

From these old techniques, vaccines utilizing selected epitopes of *Leishmania* and recombinant vaccines are being searched in several laboratories (Gillespie et al., 2016).

Vaccines have been intensely searched, and the saliva from several species of sand fly (*Phlebotomus* and American species) has an immunomodulatory effect on infection and may be useful as part of a vaccine (Kamhawi et al., 2014). Other adjuvants have been analyzed (Gonçalves et al., 2019).

For visceral leishmaniasis caused by *L. infantum*, vaccines Leishtec® and Leishmune® for the immunization of dogs have got 60–80% of protection of dogs (Oliva et al., 2014; Wylie et al., 2014), and Canileish® produced a significant reduction on the quantity of *Ph. perniciosus* fed on vaccinated dogs (Bongiorno et al., 2013). Preliminary tests on new vaccines (Leish-F1 and ChAd63-KH DNA) produced good results to protect humans against infection by *Leishmania* (Moafi et al., 2020). Specific serological biomarkers are needed to differentiate immunity against infection and that induced by Canileish® (Lima et al., 2019).

Conclusion

Due to the importance of diseases related to sand flies, which are very diversified and adaptable, these flies deserve greater attention from researchers and public health authorities. Breeding places need to be localized and delimited, and movement of adults needs to be studied, to improve barriers and control. Leishmaniasis are complex diseases, caused by several parasites and influenced by many environmental factors, by the reaction of affected hosts and the biology and physiology of vectors. Other poorly known diseases, like Carrión disease and arboviroses need to be more attentively studied and controlled. Their control can only be obtained if the epidemiology of diseases is well known in each locality and situation. New methods for the control of sand flies and related diseases, like the association of pheromones to insecticides and a better understanding of the relationship between gut microbiota and *Leishmania* would be very useful.

Acknowledgments

Glossary

Animal African trypanosomiasis (AAT) Also known as nagana or cattle wasting disease. AAT is caused by *Trypanosoma B. brucei*, *T. congolense*, *T. vivax*, *T. evansi*, and *T. equiperdum* in Africa. The former four types are transmitted by tsetse flies.

Adenotrophic viviparity Specific reproductive mechanism of *Glossina* and closely related species where larvae are nourished with secretions produced by a modified accessory gland, and live larvae develop within a common oviduct (or uterus). This reproductive strategy is a type of matrotrophic viviparity, where nutrients are provided by the mother beyond those in the oocyte before live birth.

Hippoboscoidea A dipteran superfamily that includes Glossinidae (tsetse flies), Hippoboscidae (louse flies, sheep keds), and Streblidae and Nycteribiidae (bat flies). All members reproduce by adenotrophic viviparity and feed solely on blood.

Human African trypanosomiasis (HAT) The disease caused by *Trypanosoma brucei gambiense* (Gambiense HAT, represent 98%) and *T. b. rhodesiense* (Rhodesiense HAT).

Milk gland In all Hippoboscoidea, a modified female accessory gland that provides nutritional products to the developing intrauterine larvae. All nutritional products required for larval and pupal development, beyond those in the oocyte, are provided by this gland.

Obligate hematophagy (=sanguinivory) The acquisition of nourishment by feeding exclusively on blood (hematophagy or sanguinivory).

Wigglesworthia spp. A gram-negative, obligate bacterial endosymbiont of tsetse flies. This symbiont provides specific B vitamins critical to tsetse growth and development, and stimulates the maturation and function of the fly's immune system.

Introduction

Tsetse flies (Fig. 1) represent peculiar dipteran species, and their competence as vectors of African trypanosomes make them a critical pest for human health and for agricultural development. In this article, we provide a general synopsis of tsetse fly biology covering (1) their basic ecology and physiology, (2) their ability to serve as a vector for African trypanosomes, (3) interactions with their indigenous microbiota (Weiss and Aksoy, 2011; Wang et al., 2013; Rio et al., 2016), and (4) unique aspects of their reproductive biology (Tobe, 1978; Benoit et al., 2015). These topics are followed by a discussion of strategies currently utilized to control trypanosomiasis, with a focus on methods that aim to reduce tsetse population size. This article provides an encompassing synopsis of *Glossina* biology. Throughout the article, we highlight review papers and primary literature that cover specific topics of *Glossina* biology in more detail.

Tsetse flies (Glossinidae) consist of 33 extant taxa composed of 22 distinct species (five subspecies groups) and three subgenera; *Fusca*, *Palpalis*, and *Morsitans* (Krafsur, 2009). A fourth subgenera, *Machadomia*, includes *Glossina austeni*, which based on recent studies, likely falls within the *Morsitans* group (Gooding and Krafsur, 2005; Attardo et al., 2019). *Morsitans* flies are largely savanna

Fig. 1 Female tsetse fly, *Glossina morsitans*. Photo by Geoffrey M. Attardo.

and woodland inhabitants, while *Palpalis* flies commonly reside in riverine and lacustrine habitats (Rogers and Robinson, 2004). Individuals within the *Fusca* subgenera inhabit the moist forests of West Africa with the exception of *G. brevipalpis* that has discontinuous distribution in East Africa, Democratic Republic of the Congo and Mozambique. Host specificity varies greatly between groups, and *Palpalis* group flies are anthropophilic while *Morsitans* and *Fusca* are more zoophilic. The genomes of six tsetse species, including members of all four subgenera, have been sequenced (International Glossina Genome Initiative, 2014; Attardo et al., 2019). These tsetse species exhibit significant differences in geographical distribution, habitat preferences, host choice, and in their ability to act as disease vectors (Fig. 2).

Tsetse flies are obligate blood feeders that serve as the primary cyclic vectors for old world trypanosomes, the causative agents of human and animal African trypanosomiasis (HAT and AAT, respectively) in sub-Saharan Africa. These diseases inflict profound socio-economic hardships on indigenous communities by compromising the health of humans and domesticated animals and thus hampering development across large geographic regions (Sutherland et al., 2015; Aksoy et al., 2017). HAT is caused by the protozoan parasites *Trypanosoma brucei gambiense* (Gambiense HAT, represent 98% of cases) and *T. b. rhodesiense* (Rhodesiense HAT, represents 2% of cases). *T. b. gambiense* causes a chronic form of HAT in West Africa, while *T. b. rhodesiense*, localized to eastern and southern Africa, is responsible for an acute form of the disease (Simarro et al., 2012). Both of these diseases, which are fatal if left untreated, are associated with rural areas where individuals are exposed during outdoor activities. At least 70 million people across 36 countries are at risk for HAT (Büscher et al., 2017). HAT infection progresses through two stages, the early hemolymphatic stage, during which parasites multiply and spread in the bloodstream, lymphatic system, and peripheral organs, and the late encephalitic phase when the parasites cross the blood-brain barrier and proliferate in the cerebral spinal fluid (MacLean et al., 2012; Kennedy, 2013). A HAT epidemic beginning in the 1990s has to date resulted in about 500,000 cases (Barrett, 1999; Aksoy et al., 2017). Coordinated control efforts by the World Health Organization, African governments, and other groups has reduced the number of new cases to 2000–4000 per year (Aksoy et al., 2017; Büscher et al., 2017). A current goal is the elimination of HAT by 2030, through a combination of control protocols that range from infection treatment to vector population suppression (discussed later in the article). Many more targeted reviews of HAT are available (Büscher et al., 2017; Baker and Welburn, 2018; Bottieau and Clerinx, 2019; Kennedy, 2019).

Along with the impact on human health, AAT, or nagana, is a chronic wasting disease that significantly suppresses livestock production and thus food security in sub-Saharan Africa. The two main causative agents of AAT are *T. b. brucei* and *T. congolense* (Namangala and Odongo, 2014; Morrison et al., 2016; Radwanska et al., 2018). Beyond those parasites limited to sub-Saharan Africa, others such as *T. evansi* (Desquesnes et al., 2013), *T. equiperdum* (Claes et al., 2005) and *T. vivax* (Jones and Dávila, 2001) exhibit more expansive distributions across tropical regions (Jones and Dávila, 2001). Outside of Africa, these parasites are either sexually transmitted (usually between livestock) or mechanically vectored (no biological development in the fly) by hematophagous flies other than *Glossina* (e.g. stable flies, *Stomoxys* or tabanid flies). Within Africa, *T. evansi* and *T. vivax* can be mechanically or cyclically (developmental stages occur in the fly) transmitted by tsetse flies. The economic and social burden of AAT is substantial as sustainable livestock production is suppressed, which could yield losses of US\$ 4–5 billion per year (Budd, 1999; Kristjanson et al., 1999).

***Glossina* as a vector of African trypanosomes**

To successfully transmit between vertebrate hosts, biologically transmitted African trypanosomes must complete a rigorous journey (which takes between 15 and 30 days depending on genetic and ecological factors) through their obligate tsetse vector (Rotureau and Van Den Abbeele, 2013). Specifically, upon ingestion of an infectious blood meal, “stumpy” bloodstream form (BSF) parasites pre-adapted for survival in tsetse must differentiate into insect stage procyclic form (PCF) cells and infect and replicate within the

Fig. 2 Geographical distribution of specific *Glossina* species across sub-Saharan Africa that have genomics-based resources (Attardo et al., 2019).

fly's midgut. PCF parasites then move into the tsetse's immunologically hostile cardia organ (also known as proventriculus), where they differentiate into epimastigote forms (EMF). In some flies, EMF cells are unable to advance past this stage (Vigneron et al., 2018), in which case that lineage is not transmitted to another vertebrate host and thus lost. EMF parasites that make it through tsetse's cardia migrate back into the fly's foregut and then salivary glands (SGs) where they replicate and complete their final differentiation into vertebrate-infectious metacyclics (MCF).

Despite feeding regularly on infected vertebrate reservoirs, only between 1% and 10% of tsetse harbor transmissible trypanosome infections (Aksoy et al., 2003; Abdi et al., 2017). This low infection prevalence is reflective of robust passive and active gut-associated innate immune mechanisms. Active antimicrobial immunity in tsetse's midgut involves the production of reactive oxygen intermediates (ROIs) (MacLeod et al., 2007; Vigneron et al., 2018), immune deficiency (IMD) pathway-associated antimicrobial peptides (AMPs) (Hao et al., 2003; Hu and Aksoy, 2005, 2006), peptidoglycan recognition protein LB (PGRP-LB) (Wang et al., 2009; Wang and Aksoy, 2012) and tsetse EP protein (Haines et al., 2010). Passive immunity in this environment is provided by the fly's peritrophic matrix (PM). This sleeve-like structure, components of which are constitutively secreted by tsetse's cardia organ and midgut (Lehane et al., 1996), lines the fly's midgut and separates epithelial cells from ingested products and pathogens (Hegedus et al., 2009). Mature adult tsetse with a fully formed PM are more refractory to trypanosome infection than are young adults that present an immature PM structure (Walshe et al., 2011; Haines, 2013). Furthermore, experimental depletion of PM integrity through the use of RNAi results in a significant increase in infection prevalence in otherwise resistant adults (Weiss et al., 2014). Tsetse's PM thus serves as a physical barrier that mediates the ability of trypanosomes to establish an infection in their insect vector's midgut. This structure also regulates the fly's ability to immunologically detect and respond to exogenous bacteria (Weiss et al., 2014).

Tsetse and its associated bacterial microbiota

While only a small percentage of tsetse are infected with trypanosomes, all flies house a population of indigenous bacterial endosymbionts that are intimately associated with their host's biology (Fig. 3). All tsetse harbor the obligate mutualist *Wigglesworthia*, which has been associated with the fly for 50–80 million years (Chen et al., 1999). This bacterium is found intracellularly within bacteriocytes that collectively form tsetse's bacteriome organ (located immediately adjacent to the fly's anterior midgut), and extracellularly within maternal milk (see below). *Wigglesworthia*'s chromosome encodes several complete B vitamin synthesis pathways, the products of which are likely synthesized to supplement the fly's vertebrate blood specific diet (Akman et al., 2002; Rio et al., 2012, 2019). Furthermore, *Wigglesworthia* exhibits immuno-stimulatory properties in that the bacterium must be present in developing intrauterine larvae in order for subsequent adults to present functional passive and active immune barriers (Weiss et al., 2011, 2012, 2013; Benoit et al., 2017). In addition to *Wigglesworthia*, all laboratory colonized tsetse, and most natural fly populations (Mbewe et al., 2015; Wamwiri et al., 2014; Channumsin et al., 2018; Kame-Ngasse et al., 2018 REFS), harbor a secondary commensal symbiont from the genus *Sodalis*. *Sodalis*' acquisition by tsetse is relatively recent (~1 million years; Aksoy et al., 1997), and strains from different tsetse species are closely related, suggesting horizontal transmission or recent independent acquisition of the symbiont (Aksoy et al., 1997; Toh, 2005). The bacterium resides both intracellularly and extracellularly within tsetse's midgut, hemolymph and salivary and milk glands. *Sodalis*' function within tsetse is largely unknown, although it has been associated with fly longevity (Dale and Welburn, 2001) and susceptibility to trypanosome infection (Welburn et al., 1993; Dale and Welburn, 2001). Finally, some tsetse populations house parasitic *Wolbachia* and *Spiroplasma* (Doudoumis et al., 2017; Schneider et al., 2019), both of which likely induce host reproductive abnormalities.

Field-captured tsetse house a midgut-associated population of environmentally acquired microbes (Geiger et al., 2009, 2010; Lindh and Lehane, 2011; Aksoy et al., 2014; Griffith et al., 2018). This microbial population is transient and comprises only a small percentage of the fly's total microbiota. The functional role of tsetse's environmentally acquired microbes is currently unknown.

Tsetse fly ecology, feeding, and metabolism

General characteristics

Although tsetse flies have overlapping distribution across sub-Saharan Africa, different species often reside within distinct ecological niches. Tsetse are divided into three major ecological groups that consist of savannah (*Morsitans* sub-genus), riverine (*Palpalis* sub-genus), and forest (*Fusca* sub-genus)-associated species (Fig. 4). The general trend is that those of the *Palpalis* and *Fusca* groups prefer relatively moist regions with denser vegetation cover, while the *Morsitans* group prefers more open areas. The specific ecological

zones have also been divided based on levels of aridity, where *Morsitans* flies prefer arid to semi-arid regions, *Fusca* flies in sub-humid to humid areas, and *Palpalis* flies from semi-arid to humid regions (Jahnke and Jahnke, 1982; Leak, 1999). Specific vegetation types are associated with each species, which they utilize mostly as resting sites (Challier, 1982; Leak, 1999). Choice of resting site varies significantly on both daily and seasonal cycles, and a major contributing factor is thermoregulation and maintenance of water balance (MacLennan et al., 1972; Turner, 1980). Specifically, tsetse will reside on the sunny side of vegetation during cool periods and retreat into lower, shaded areas during warmer times (Laveissière et al., 1978; Challier, 1982). The preferred height of vegetation resting sites varies between species but does show a general trend that as plant height increases the numbers of resting tsetse decrease. In addition, resting sites are at lower heights during the day and the dry season (Challier, 1982; Leak, 1999). Larviposition sites vary between species within the three sub-genera, but most females deposit their larvae in shaded areas with soil qualities that facilitate larval burrowing (Challier, 1982; Leak, 1999). Extensive details on tsetse fly ecology can be found in reviews by Challier (1982) and Leak (1999).

Circadian biology and seasonality

Daily rhythms and seasonality are critical to tsetse fly biology. Multiple aspects related to tsetse's behavior and physiology have been examined in relation to circadian rhythms (Brady, 1972a, 1972b; Nash and Trewern, 1972; Crump and Brady, 1979; Van der Goes van Naters et al., 1998). An excellent review of tsetse fly circadian biology examined key rhythmic aspects among multiple *Glossina* species (Brady, 1988). Most aspects of tsetse biology exhibit a U-shaped pattern, with increased general activity, such as host seeking and probing, occurring more frequently during dawn and dusk (Fig. 5). The impact of starvation will increase the peaks of activity, while feeding and pregnancy status will suppress daily changes (Brady, 1988). Importantly, not all biological characteristics of tsetse flies have the U-shaped pattern. For example, larviposition and eclosion occur more frequently in the evening (Fig. 5). Seasonal changes in rainfall and temperature exert significant behavioral and physiological changes across *Glossina* species (Challier, 1982). Additionally, microclimates, local vegetation, and the movement/availability of potential hosts have a significant impact on local tsetse population density during each season (Hargrove and Vale, 1980; Diallo, 1981). Climate change is predicted to have a significant impact on the survival and distribution of *Glossina* across Africa (Kleynhans and Terblanche, 2011; Messina et al., 2012; Lord et al., 2018).

Host location

Tsetse flies locate and decide to feed on their host through a combination of visual, thermal, olfactory, and tactile cues (Torr, 1989, 1990; Torr et al., 1995; Tirados et al., 2011; Soni et al., 2019). Vision and olfaction are the two most well studied aspects of tsetse host seeking. Recent genome sequencing has allowed the identification of the chemosensory genes and significant process has been made in tsetse chemosensation (Obiero et al., 2014; Macharia et al., 2016). Many specific host derived chemicals have been examined for their ability to attract tsetse flies (Vale, 1980; Vale and Hall, 1985; Torr and Vale, 2015). Most of these studies focused on the identification of artificial baits for traps or repellents for animals or humans (Wachira et al., 2016). The specific odorants that have attractant properties can be divided into those derived from animal breath (acetone, octenal, CO₂), skin (sebum-based), and urine (phenols). Recent studies have examined the response of *Glossina* to chemical cues at the molecular and sensilla levels (Chahda et al., 2019; Soni et al., 2019), where these analyses have linked specific sensilla and molecular receptors to both chemical cues and repellants (e.g. CO₂-sensitive basiconic sensilla were identified). These combinatory analyses are likely to improve traps to increase tsetse capture rate and be able to target multiple *Glossina* species. As an example, 2-propanol was identified as a target that would effectively trap two tsetse fly species, *G. morsitans* and *G. fuscipes* (Chahda et al., 2019).

Visual and thermal cues are critical for tsetse flies to locate a host (Torr, 1989; Vale, 1993). Black and blue colored targets, as opposed to those of lighter color (red, yellow, and white), are preferred tsetse landing sites. Specific shapes, patterns, and the movement of targets are more or less desirable depending on the specific characteristics (Torr, 1989; Tirados et al., 2011; Torr et al., 2011; Lindh et al., 2012). A lack of UV reflectance from the materials is likely a critical aspect in relation to attraction (Lindh et al., 2012). Thermal cues, along with CO₂, likely act as close range cues prompting *Glossina* landing (Willemse and Takken, 1994; Lazzari, 2009).

Host preference

The combination of the above-described host cues, along with animal availability, likely allows each tsetse fly species to feed on their preferred hosts. Studies on tsetse host preference have used observation of feeding patterns, serological assays (such as an enzyme-linked immunosorbent assay, ELISA), and more recently, molecular analysis of bloodmeals (Clausen et al., 1998; Leak,

Fig. 5 Circadian rhythm changes in tsetse flies in relation to the biological status of these flies. Data is based upon previous studies that have assessed daily changes in tsetse fly behavior (Crump and Brady, 1979; Brady, 1988). Photophase is in hours since midnight. *Visual*, response to moving stimuli; *Biting*, probing by tethered male on warm sponge ball; *Olfactory*, response to human body odor; *Starvation*, increases general activity without altering the higher levels at dawn and dusk; *Eclosion*, adult emergence; *Larviposition*, female birth.

1999; Njiokou et al., 2004; Steuber et al., 2005; Auty et al., 2016; Gaithuma et al., 2020). Importantly, ingestion of blood from multiple host types serves as an adequate source of nutrients for tsetse (Moloo et al., 1988). Thus, the nutritional value of blood does not appear to mediate tsetse host selection. Early findings based upon precipitin ring or haemagglutination inhibition tests established five *Glossina* groups based upon feeding profiles (Weitz, 1963). Group 1: Species that feed mainly on Suidae (*G. swynnertoni*, *G. austeni*, *G. tabaniformis*, *G. fuscipleuris*), Group 2: Species that feed on both Suidae and Bovidae (*G. morsitans morsitans*, *G. m. submorsitans*), Group 3: Species that mainly feed on Bovidae (*G. pallidipes*, *G. longipalpis*, *G. fusca*), Group 4: Species that feed on mammals other than pigs and bovids (*G. longipennis*, *G. brevipalpis*), and Group 5: Species that feed on the most available species, including humans (*G. palpalis palpalis*, *G. fuscipes fuscipes*, *G. tachinoides*). Local variations do occur, where the main host species for a specific tsetse fly species is replaced by another more abundant or other preferred host species (Moloo, 1993; Clausen et al., 1998). Interestingly, some abundant animals, such as zebra, are not used by tsetse as hosts (Moloo, 1993; Clausen et al., 1998). This is likely due to specific host cues (Olaide et al., 2019) and striped colors that disrupt landing of flies (Caro et al., 2019). More details on tsetse host preference has been reviewed by Moloo (1993), Leak (1999), and Clausen et al. (1998).

***Glossina* feeding, digestion, and metabolism**

Following host location, heat and humidity cues induce tsetse flies to commence skin probing behaviors (Chappuis et al., 2013). Tsetse may probe multiple sites on a host before beginning to feed (Leak, 1999). Chemical stimuli detected by the fly's mouthparts, such as ATP (Margalit et al., 1972; Rice et al., 1973), are also likely to stimulate feeding. While probing and feeding, *Glossina* will discharge saliva into the host. Early studies identified that this saliva is important to the process of feeding, and recent projects have identified most of the major components of tsetse saliva (Telleria et al., 2014; Matetovici et al., 2016). Salivary gland enriched genes, which consist predominantly of highly expressed secreted peptides, were identified through the use of RNA-seq (Telleria et al., 2014; Matetovici et al., 2016). Multiple proteinaceous components of tsetse saliva have been assigned functions, including anticoagulant activity, DNA/RNA nucleic acid binding, suppression of platelet aggregation, and allergenic activities (Mant and Parker, 1981; Cappello et al., 1996; Li and Aksoy, 2000; Li et al., 2001; Alves-Silva et al., 2010). When tsetse flies have salivarian trypanosome infections, many, if not all, of the salivary proteins are reduced at the transcript, and likely protein, level (Telleria et al., 2014; Matetovici et al., 2016). This decrease in saliva proteins is likely due to trypanosome-induced immune and stress responses within the tsetse fly SGs (Telleria et al., 2014; Matetovici et al., 2016). The reduced levels of saliva proteins underlie inefficient and more frequent feeding (Van Den Abbeele et al., 2010), which is likely to increase parasite transmission.

Tsetse flies feed exclusively on vertebrate blood, which contains abundant proteins and lipids but few carbohydrates. Recent observations suggest that tsetse flies may also utilize plant-derived sugars as a nutrient resource (Solano et al., 2015). However, the ecological importance of this finding has yet to be established and it has yet to be validated by other research groups. The size of tsetse blood meals is species and sex specific (Moloo and Kutuza, 1970; Taylor, 1976), and the large volume of warm blood ingested can cause thermal stress (Lahondère and Lazzari, 2015; Benoit et al., 2019). When the blood is ingested, most flows past the cardia into the crop, causing the fly to become reddish immediately after feeding. As blood passes back through the cardia it becomes encased within the fly's PM. This structure acts to prevent direct interaction between components of the blood meal and the fly's midgut epithelium (Hegedus et al., 2009). Importantly, tsetse's PM also plays a critical role in the ability of trypanosomes to establish an infection in tsetse's midgut and migrate to the fly's SGs from which they transmit to a new vertebrate host (Weiss et al., 2014; Aksoy, 2019; Rose et al., 2020; Vigneron et al., 2020). While in the gut, the blood meal will become a darker brown as digestion advances. The bloodmeal consists mostly of water, which is rapidly excreted (a few hours) via diuresis after the termination of feeding (Benoit et al., 2014b). This is a common physiological strategy among blood feeding insects to reduce excess water from blood feeding (Benoit et al., 2014c).

Following elimination of excess water, digestion occurs through a suite of specific digestive enzymes that break down lipids and proteins (Langley, 1967; Leak, 1999). Early studies on this process were conducted by Sir Vincent B. Wigglesworth (1929) and a synopsis of tsetse digestive processes can be found in Leak (1999). The full suite of proteins involved in tsetse digestion have now been thoroughly characterized by transcriptome studies (Bateta et al., 2017). The initial process involves the breakdown of red blood cells by hemolysin (Gooding, 1977). This process is followed by the secretion of multiple peptidases and proteinases, which act to induce rapid digestion of the proteinaceous components of the blood. Free amino acids and lipids generated from the breakdown of blood are used to accumulate lipid reserves. The process of lipid accumulation is critical to success of tsetse's pregnancy cycle, as lipids are a prominent component of the milk that pregnant female flies generate to feed their intrauterine larvae (more information provided below, Moloo, 1976a, 1976b; Benoit et al., 2015). Intervals between feeding events vary from 36 h to nearly 5 days depending on environmental conditions (Leak, 1999). The process of digestion occurs most rapidly at higher temperatures (McCue et al., 2016), but more efficient digestion decreases the ability of the flies to tolerate starvation and dehydration between each blood meal. Waste products generated include excess ions, specific amino acids, and nitrogenous waste that is excreted in the form of uric acid (Leak, 1999).

An interesting physiological consequence of tsetse's reliance on vertebrate blood as its sole nutrient source is the fly's transition to utilizing proline as energy to fuel metabolically expensive reproductive processes and flight (Bursell, 1977, 1981; Michalkova et al., 2014b). Specifically, tsetse converts proline to alanine within muscles (and other organs), which provides biochemical products that can be utilized in the tricarboxylic acid cycle. This process represents a substantial variation from other dipteran systems, which rely on carbohydrate-based factors (mainly trehalose) as a rapid source of energy necessary for activities such as flight (Wyatt and Kale, 1957; Bursell, 1981; Thompson, 2003). Tsetse catabolize lipids to produce acetyl-CoA in their fat body, which

facilitates the regeneration of proline from alanine (McCabe and Bursell, 1975; Bursell, 1977; Norden and Matanganyidze, 1977). The process of proline metabolism is controlled by the release of adipokinetic hormone (AKH) from the corpora cardiaca (Pimley and Langley, 1982; Attardo et al., 2012; Caers et al., 2016). Proline homeostasis is critical to the survival of procyclic trypanosomes that reside in tsetse's midgut, and interference with the metabolism of this amino acid prevents *T. brucei* from establishing an infection in the fly's midgut. Specific B vitamins generated by obligate *Wigglesworthia* are required to maintain proline homeostasis (Michalkova et al., 2014b), and when this symbiont is eliminated via antibiotic treatment, homeostasis of tsetse nutrient reserves and circulating proline becomes impaired. The critical metabolic roles of proline in tsetse and trypanosome biology highlight the importance of this amino acid in relation to nutritional homeostasis of this vector-pathogen system.

Tsetse fly life cycle

Basic characteristics of *Glossina* viviparity

Tsetse flies reproduce via a process called "matrotrophic viviparity." In this case nutrients are provided by the mother to her developing intrauterine larvae (Tobe, 1978; Benoit et al., 2015). This form of reproduction has also been described as "adenotrophic viviparity," which is defined as 'glandular fed before live birth' and is a more tsetse-specific designation. This reproductive strategy represents a marked deviation from oviparity (egg laying) used by most insect systems that do not provide nourishment beyond the embryonic (egg) stage. Although rare, evolution of live birth systems across insects has occurred multiple times (Kalinka, 2015). In utero larvae are provided nourishment in the form of milk that is secreted from specialized glandular organs (Hagan, 1951; Benoit et al., 2015). Adenotrophic viviparity is a common characteristic among the superfamily Hippoboscoidea, which includes bat flies and sheep keds (Lenoble and Denlinger, 1982; Meier et al., 1999).

Tsetse have undergone three significant morphological adaptations that facilitate their reproduction via adenotrophic viviparity (Fig. 6). First, tsetse ovaries only produce a single oocyte per gonotrophic cycle. Second, the reproductive tract has been greatly expanded and surrounded by tracheated, muscle-lined epithelial cells that collectively compose the uterus (Tobe, 1978; Pellegrini et al., 2011; Benoit et al., 2015). Within the uterus, cuticular projections form horns, known as the choriothete, that serve to remove the egg chorion and larval cuticle and anchor the larvae in the correct position to ensure it can properly feed (Saunders, 1960; Tobe and Davey, 1971; Pellegrini et al., 2011). The last modification is that the female accessory gland is expanded from a few cells common in other fly systems (Attardo et al., 2014) into a large, branched organ consisting of thousands to millions of cells (Hagan, 1951; Tobe, 1978; Benoit et al., 2015).

Females deposit a single larva each gonotrophic cycle (GC) (Tobe, 1978; Benoit et al., 2015). Mating, which usually occurs within a week of adult emergence, involves the male-to-female transfer of a spermatophore that contains sperm and a multitude of *Glossina*-specific proteins (Scolari et al., 2016; Attardo et al., 2019). Many of these proteins are derived from the male accessory gland (Scolari et al., 2016) and are likely to impact female receptivity to males and sperm viability. Oogenesis and ovulation usually occur within the first 10 days following adult emergence, details of these processes have been described in (Benoit et al., 2015). Embryogenesis (3–4 days) occurs within the uterus followed by larvigenesis (5–6 days). During embryogenesis and larvigenesis, development of the second oocyte progresses in the ovary so ovulation can occur within 30–35 min after birth of the fully developed larva (Denlinger and Ma, 1974; Benoit et al., 2018). The first larvae are deposited after 20 days and immediately burrow into the surrounding substrate and pupate (Tobe, 1978). Subsequent larvae are deposited every 9–10 days, with the duration between births extending and the quality of the offspring declining as the female ages (Michalkova et al., 2014a; McIntyre and Gooding, 1998). Oogenesis alternates between the two ovaries during each GC. The period of each reproductive cycle is influenced by factors such as blood quality, time between meals, and exposure to stress that can slightly reduce or significantly extend each reproductive cycle (Tobe, 1978; Hu et al., 2008). Additionally, the length of tsetse's GC significantly increases if the fly is infected with trypanosomes (Hu et al., 2008). Specific details on *Glossina* reproductive biology have been reviewed by Tobe (1978) and Benoit et al. (2015).

Glossina milk production

One of the more unique aspects of tsetse biology is the provisioning to nutritive secretions (fly milk) to developing intrauterine larvae. Tsetse larvae grow over 100-fold (dry mass) during each cycle of larvigenesis (Denlinger and Ma, 1974; Langley and Pimley, 1975). The fat body and milk gland are both critical to this process, as lipid reserves are mobilized from the fat body and milk proteins and other factors are produced by the milk gland (Langley et al., 1981; Attardo et al., 2012; Baumann et al., 2013). Tsetse milk is mostly water (80–85%), and the caloric portion consists of proteins and lipids (Cmelik et al., 1969). The protein components of tsetse milk consists of a lipocalin (Attardo et al., 2006), eight or nine *Glossina*-specific novel milk proteins (Benoit et al., 2014a), transferrin (Guz et al., 2007), acid sphingomyelinase (Benoit et al., 2012), and other minor constituents (Wang and Aksoy, 2012; Benoit et al., 2014a; Attardo et al., 2019). The 12 genes encoding the primary tsetse milk proteins account for nearly 50% of all mRNAs transcribed by lactating female flies (Benoit et al., 2014a). Similar levels of significant transcriptional investment have been noted in other matrotrophic insects (Jennings et al., 2020). Water and other smaller ions are incorporated into the milk via channel proteins, such as aquaporins (Benoit et al., 2014b). *Wigglesworthia* and *Sodalis* are found extracellularly in maternal milk secretions, which serve as the route through which these microbes are trans-generationally transmitted (Wang et al., 2013). *Wolbachia* and *Spiroplasma* are transmitted via the germline (Balmand et al., 2013; Doudoumis et al., 2017).

Fig. 6 Female reproductive biology of *Glossina*. (A) First gonotrophic cycle of a *Glossina morsitans* female under optimal environmental and nutritional conditions. Oogenesis, embryogenesis, and larvigenesis within the *Glossina* reproductive system (ovaries and uterus) are shown. (B) Diagram of a reproductive tract during lactation. (C) Cross section of milk gland during lactation and following involution during the dry (non-lactating) period.

The process of milk production is regulated by the dynamics between insulin signaling, juvenile hormones (JH) and ecdysteroids, where higher JH levels are associated with a non-pregnant/lower milk production status (Baumann et al., 2013). A reduction in JH levels may be a convergent mechanism used during extended viviparity, as similar hormonal dynamics are observed in distantly related viviparous insect species (Jennings et al., 2020). The process of birth (=parturition) is likely prompted by input from the mother and intrauterine larvae and regulated by an increase in ecdysteroids and parturition hormone that prompt birth (Denlinger et al., 1983; Robert et al., 1986; Zdárek and Denlinger, 1997). A rapid autophagic breakdown of the milk gland (=involution) occurs immediately after birth, which is critical to allow for recovery between pregnancy that allows the replenishment of nutrient

reserves (Benoit et al., 2018). As with the termination of pregnancy, the involution period is triggered by increased ecdysteroids that precedes parturition.

Prevention and control of tsetse flies and trypanosomiasis

The control of African trypanosomiasis involves the integration of multiple strategies, and this is complicated by the fact that AAT and HAT are very different from an epidemiological perspective. Specifically, a large diversity of wild and domesticated animals can serve as a reservoir for AAT-causing trypanosomes as well as those that cause HAT in east Africa (i.e. *Trypanosoma brucei rhodesiense*). Conversely, parasites that cause west African HAT (i.e. *T. b. gambiense*) circulate only through humans, and to the best of our knowledge no other animals serve as reservoirs (Franco et al., 2014). Independent of the trypanosome species, HAT and AAT are best controlled via three specific routes: (1) reducing disease incidence and burden in vertebrate hosts, (2) controlling populations of the tsetse fly vector, and (3) inhibiting trypanosome development and subsequent transmission by tsetse flies (Fig. 7) (Aksoy et al., 2017). Limited progress has been made regarding reducing/eliminating and/or treating vertebrate disease. This largely reflects the lack of anti-trypanosomal vaccines, due to the phenomenon of trypanosome antigenic variation (Bangs, 2018). Anti-trypanosomal chemotherapeutics present limited effectiveness. Encouragingly, progress is being made on the development of both anti-trypanosomal vaccines (Vigneron et al., 2020) and drugs (Field et al., 2017; Pollastri, 2018). Detection of the parasite within vertebrate hosts is expensive and logistically difficult due to the lack of testing capabilities, the reliance on clinical manifestation of trypanosome infection, and the large number of potentially infected livestock (Mumba Ngoyi et al., 2014; Jamonneau et al., 2015; Koffi et al., 2016; Aksoy et al., 2017). The importance of detection is critical, as current treatments are toxic to vertebrates and parasites quickly develop resistance (Babokhov et al., 2013; Aksoy et al., 2017; Fairlamb and Horn, 2018). The development of novel treatments, such as nifurtimox combination therapy (NECT) (Priotto et al., 2009; Babokhov et al., 2013), is likely to improve the safety and effectiveness of treatment. Chemotherapy is predominantly used to control AAT (Giordani et al., 2016), but resistance due to limited chemical options is becoming more common. *Trypanosoma*-resistant livestock breeds have been noted and represent a potential solution for AAT (Bocoum et al., 2012; Berthier et al., 2016; Yaro et al., 2016), but asymptomatic infections could allow these resistant animals to serve as reservoirs.

Tsetse control is an effective means of controlling disease transmission, largely because female tsetse produce so few offspring over the course of their lifespan (10–12 offspring compared to thousands of eggs produced by other vector systems; Benoit et al., 2015). Vector control is essential for both AAT and Rhodesiense HAT, but has not been used as significantly for Gambiense HAT (Solano et al., 2013; Aksoy et al., 2017). Even though not uniformly used, modeling indicates that tsetse population control should be included as a critical component for the elimination of African trypanosomiasis (Hargrove et al., 2012; Aksoy et al., 2017; Rock et al., 2018). Sterile insect technique (SIT) is under consideration for continent-wide control, but the cost due to the diversity of species that transmit trypanosomes, along with the necessary infrastructure and logistics, make feasibility difficult (Kabayo, 2002; Rogers and Randolph, 2002; Aksoy et al., 2017; Sutherland et al., 2019). Despite these challenges, SIT was successfully used to eradicate *G. austeni* from Unguja Island, Zanzibar (Vreysen et al., 2000). Trapping and insecticide treatments have proven to be much more cost effective on mainland Africa. Recent progress has been made on the development of smaller, more effective insecticide-impregnated targets that are effective and easier to deploy when compared to large targets that have been used in previous control programs (Courtin et al., 2015; Shaw et al., 2015). Habitat manipulation (= bush clearing) was used in early control programs for the reduction of tsetse fly presence, which included the removal of specific vegetation near villages or farms

Fig. 7 Prevention on trypanosomiasis and suppression of tsetse populations in relation to human and livestock hosts. Each point in bold (top) represents a method that has been used to interfere with the transmission cycle. Points on bottom represent potential control methods.

(Challier, 1982; Leak, 1999; Keating et al., 2015). This was only minimally successful and re-invasion occurred fairly quickly. Also, bush clearing to reduce tsetse population density did not outweigh the negative side effects such as soil erosion (Lloyd et al., 1933). The use of fly repellent, wearing thick clothes that prevent the proboscis from reaching the skin, insect barriers (e.g. netting), and reduced activity outside of peak periods of tsetse activity (dawn and dusk) are other mechanisms that help to suppress trypanosomiasis by reducing *Glossina* feeding (Challier, 1982; Uilenberg and Boyt, 1998; Leak, 1999; World Health Organization, 2013; Keating et al., 2015).

Of importance is that following reduction/elimination, tsetse populations should be monitored to ensure that re-establishment does not occur (Gooding and Krafur, 2005; Davis et al., 2019), specifically since tsetse migration and population differences are likely to have significant impact on suppression of African trypanosomiasis by *Glossina* control (Aksoy et al., 2013; Ndeffo-Mbah et al., 2019). The sequencing of six tsetse species genomes provides insight into tsetse's olfactory biology, thus leading to the identification of targets for the development of novel attractants and/or repellents (International *Glossina* Genome Initiative, 2014; Obiero et al., 2014; Macharia et al., 2016; Attardo et al., 2019). Additionally, this genomic information will facilitate the development of novel control strategies aimed at reducing tsetse fecundity (Benoit et al., 2014a, 2015; Scolari et al., 2016; Attardo et al., 2019) and/or interfering with the interwoven tsetse/endosymbiont relationship for the purpose of enhancing the fly's innate anti-trypanosomal immunity (Weiss et al., 2011; Michalkova et al., 2014b; Benoit et al., 2017; Bing et al., 2017; Attardo et al., 2019). These newly developed resources are likely to provide novel, *Glossina* specific targets for vector control programs.

Genetic manipulation could be used to control tsetse or inhibit trypanosome development within the fly. Direct genetic manipulation of *Glossina*, as has been used successfully in a multitude of other insect systems (Shaw and Catteruccia, 2019; Raban et al., 2020), is unlikely to work in tsetse because the process would involve removal and injection of eggs found in the maternal uterus. Treated eggs would require implantation into another female at the same pregnancy stage. An alternative that could prove successful is injection of genetic materials into the female that are incorporated into the germline, which has been successful in other insects (Chaverra-Rodriguez et al., 2018; Macias et al., 2020). A major issue for producing genetically modified *Glossina* is that any reduction in reproductive output would make prolonged rearing of a specific line nearly impossible due to the reduced number of larvae produced by a single female under optimal rearing conditions (Gooding et al., 1997).

Two microbial-based methods have been suggested to control tsetse. First, *Wolbachia*-based cytoplasmic incompatibility (CI) has been noted (Alam et al., 2011), and this method could be used to suppress tsetse fly populations. However, this control strategy may be inefficient for *Glossina*, as population genetics-based studies suggest that *Wolbachia* infections are low density and CI has little influence on population structure (Symula et al., 2013). Second, paratransgenesis through the genetic modification of tsetse's secondary symbiont, *Sodalis*, has been suggested as a mechanism to suppress *Glossina* populations and/or interfere with tsetse-trypanosome interactions (Aksoy et al., 2008; Weiss and Aksoy, 2011; Medlock et al., 2013; Kariithi et al., 2018). Proof-of-concept paratransgenesis studies have been conducted with *Sodalis* that produce anti-trypanosome factors (De Vooght et al., 2012, 2014).

Concluding remarks

Tsetse flies are unlike many other flies because they feed solely on vertebrate blood and reproduce by adenotrophic viviparity. Their slow reproductive rate suggests that insect control protocols should be more successful than in other systems. This has not been the case as most tsetse fly control programs have failed in the long term. Prolonged suppression of flies and the prevention of African trypanosomiasis will require a multi-targeted approach that relies heavily on fly control along with treatment of vertebrate hosts followed by population monitoring to ensure elimination of both flies and the trypanosomes. These targeted approaches will require continual research on this pest to ensure an increasing toolbox of techniques to suppress tsetse flies if resistance to current control methods develop.

Taxonomy and Identification

The Ceratopogonidae are a family of small flies (generally 3–4 mm in length) belonging to the order Diptera, Suborder Nematocera, infraorder Culicomorpha and superfamily Chironomoidea. They are closely related to the Chironomidae (commonly known as non-biting midges) but can be easily distinguished from them by the presence of biting mouthparts, short forelegs, wings kept flat on the abdomen and folded like a closed scissor when the insect is resting, characteristic wing venation and by the lack of the two thoracic and abdominal pseudopods in the larvae. Ceratopogonids are commonly known as biting midges, but are also called biting gnat, punkies, no-see-ums or sandflies, although this last name is best reserved for Phlebotominae.

The Ceratopogonidae counts over 6200 species comprised in 112 extant genera (Borkent, 2016a,b). The Ceratopogonidae family is divided into four subfamilies: Leptoconopinae (2 genera), Forcipomyiinae (2 genera), Dasyheleinae (1 genus) and Ceratopogoninae (107 genera). Adults have multi-segmented antennae (14–15 articles), wings with reduced venation and concentration of the radial ones in the coastal area, which allow the distinction of the Ceratopogonidae from the other Diptera. Taxonomic keys, at genus level, for adult ceratopogonids are provided by Wirth et al. (1974), Downes and Wirth (1981), de Meillon and Wirth (1991), and Borkent and Spinelli (2007). The immature stages of Ceratopogonidae are poorly known, but the larvae of many genera, including *Culicoides*, have been described by Kettle and Lawson (1952), Blanton and Wirth (1979), and Glukhova (1979, 1989).

The most important genus in this family is *Culicoides*, which includes species that are vectors of well-known animal diseases. The first description of a species of *Culicoides* dates back to 1713 by W. Derham, Rector of the University of Upminster in Essex in England, in his work entitled “Physico-Theology: or a demonstration of the being and attributes of God, from His Work of Creation” and dedicated to the Archbishop of Canterbury. In his work, Derham described the species *Culex minimus nigricans maculatus sanguisuga* as “...it is about one tenth of an inch, or somewhat more, long, with short antennae. It is spotted with blackish spots especially on the wings. ... It comes from a little slender eel-like worm of a dirty white colour, swimming in stagnating waters by a wriggling motion.” The genus *Culicoides* was later created by Latreille in 1809. Several small characteristics distinguish the members of this genus from the other ones of the Ceratopogonidae family: (i) presence of two small humeral pits near the front edge of the thorax, (ii) empodium vestigial or extremely small between tarsal claws, which are the same size and toothless, (iii) two small and narrow radial cells at the end of radial vein in the wings. However, the most important feature is the presence of spots on the wings, which represent one of the main morphological characters used in the species identification.

To date, the genus *Culicoides* counts over 1340 species (Borkent, 2016a) of which about 60 are implicated as vectors of pathogens and parasites to humans and livestock (Borkent, 2004). The subgeneric classification is based almost exclusively on the morphology of adults and counts 31 subgenera (Harrup et al., 2015). The most abundant group is subgenus *Oecacta* followed by the subgenus *Avaritia* which contains a wide proportion of vector species of viruses affecting livestock. As reported by Borkent (2004), the *Culicoides* fauna of some regions of the world has been poorly studied, so that many species remain to be described. Furthermore, although a number of very good systematic studies exist, a refined taxonomy using morphological and genetic techniques is essential to understand the relationships between *Culicoides* species. In the last decades, molecular analyses and phylogenetic studies have helped to discriminate the morphologically cryptic species belonging to a complex of similar species, such as *Culicoides variipennis* complex, *Culicoides obsoletus* complex and *Culicoides pulicaris* complex (Holbrook et al., 2000; Meiswinkel et al., 2004; Nolan et al., 2007; Nielsen and Kristensen, 2015). These studies will provide a more accurate framework to elucidate distribution, ecology, phenology, biting habits, vector capacity and other characteristics of harmful species.

Some useful works for the *Culicoides* identification at species level are provided by Khamala and Kettle (1971), Boorman and Dipeolu (1979), Glick (1990), and Meiswinkel (1995) for Afrotropical fauna; by Tokunaga (1962), Dyce et al. (2007), Bellis

(2013), and Bellis et al. (2015) for Australasian fauna; by Blanton and Wirth (1979), Downes and Wirth (1981), Wirth et al. (1985), and Holbrook et al. (2000) for Nearctic fauna; by Aitken et al. (1975), Wirth et al. (1988), and Felipe-Bauer et al. (2003) for Neotropical fauna; by Kitaoka (1985a,b), Wirth and Hubert (1989), and Bellis (2014), for Oriental fauna; by Campbell and Pelham-Clinton (1960), Kremer (1965), Delécolle (1985), and Glukhova (2005) for Palaearctic fauna. Generic keys for larvae are published by Jamnback (1965), Glukhova (1977, 1979), and Murphree and Mullen (1991). Useful indications for taxonomic identification of *Culicoides* pupae were provided by Borkent (2014).

Morphology

Culicoides eggs are tiny (0.3–0.5 mm in length) and banana shaped (Fig. 1). As soon as laid they are white in color, and subsequently turn dark brown. The membrane surface is covered with minute projections used for adhering the eggs to the substrate.

Culicoides larvae are translucent white and approximately 2–5 mm long (Fig. 2). They are worm-like and move resembling small eels. Larvae have a well chitinized yellow-brown head, a thorax consisting of three segments and an abdomen with nine segments. Two maxillae and two mandibles, normally retained into cephalic capsule and everted to scrape and/or rip the substrate during feeding, are evident in the anterior position of the head (Fig. 3). The pharyngeal apparatus, a sclerotized structure formed by epipharynx and hypopharynx, is observed inside the buccal cavity (Fig. 4). These structures bear combs used to crush and strain ingested food. The shape and number of combs is related to the feeding behaviors and varies according to the species. At the caudal end, setae are present to enhance the larval mobility. Bifid anal papillae are retracted in the anus and can be everted to help osmoregulation and larval movement (Fig. 5).

Fig. 6 *Culicoides* biting midge, pupa. Photo credit: Cipriano Foxi.

The pupae, 2–4 mm long, are brown in color, with a pair of prothoracic horns used for breathing (Fig. 6). In aquatic forms, thin spiral openings at the ends of these respiratory tubes, allow the pupae to breathe on the water surface.

Culicoides adults are small flies with a body measuring 0.8–3 mm in length (Fig. 7). Most of the head is occupied by compound eyes made up of numerous ommatidae separated by small spaces, which in some species are covered by a fine pubescence. The 15-segmented adult antennae show a basic structure with scape, pedicel and flagellum consisting of 13 segments. In the female antennae, the flagellum has the first height segments ovoid and the last five elongated. The male antennae are more plumose and only the last three flagellomeres are elongated. The antennae bear five types of sensilla (Fig. 8):

- ampullacea: small deep dimples internally hosting a bulb-shaped sensillum in the center;
- trichodea: transparent, long or short bristles; they have no articulated insertion;
- chaetica: long and dark bristles characterized by a flexible membrane at the insertion point with the antenna. In females these sensilla are abundant in short articles (3–10 segments). In males they form the plume;
- basiconica: short and transparent bristles, numerous in long segments;
- coeloconica: small depression with a rounded protuberance in the center surrounded by several microtrichi. They probably function as hygroreceptors or olfactoreceptors.

The number and the distribution of these sensory pits in the antennal segments, particularly the coeloconic sensilla, are useful taxonomic characters. Furthermore, it seems that the number of antennal flagellomeres bearing sensilla coeloconica correlates with

Fig. 8 *Culicoides* biting midge, antennal sensilla. (A) Ampullacea, (B) coeloconica, (C) basiconica, (D) trichodea long, (E) chaetica. Photo credit: Cipriano Foxi.

the host preference. Indeed, *Culicoides* that feed on birds have more sensilla distributed in almost all segments while mammalophilic species tend to have fewer flagellomeres with sensilla coeloconica.

The mouthparts, located below the antennae, consist of an upper labrum or epipharynx, a pair of mandibles, a pair of maxillary laciniae, a hypopharynx and a labium (Fig.9). In the females, mandibles and lacinia bear a row of teeth near the tip which are used to cutting skin. The hypopharynx is covered for its entire length by the salivary groove, while, distally, it is rounded with teeth to facilitate penetration in the skin. A pair of maxillary palps is connected with the mouthparts. The maxillary palps are 5-segmented with the third segment bearing a sensory pit rich of sensilla (Fig. 9). The males have mouthparts reduced to feed on sugar sources.

The thorax is moderately broad and hooped above, extending very slightly over the head. The wings are short, relatively broad, and covered by minute hairs with a density which gives rise to pigmentation patterns. The presence/absence of clear and dark spots as well as their shape, size and distribution in the wings are morphological characters used to discriminate the different species. The 9-segmented abdomen is yellowish brown in color, and slightly tapered at the end. In females, the abdomen ends with two cerci covered by short hairs. The spermathecae, ranging one to three, are often joined to a common duct through a small sclerotized ring. The male abdomen ends with the hypopygium (male genitalia), which consists of an aedeagus, two parameres and, laterally, of two triangular apicolateral expansions of the 9th segment, basistyle and dististyle (Fig.10). Shape and size of the aedeagus and parameres are the most important taxonomic characters for species identification.

Life cycle

Biting midges grow through the typical development cycle of nematoceros flies consisting of egg, four larval instars, pupa and adult. Females begin to lay up to 400 eggs at 3–4 days post blood feeding. Mostly of the midge species produce 2–4 clutches with an average of 80–100 eggs at each oviposition. The eggs hatch at 2–7 days post spawning. The larvae through four instars before pupation. Larval development time is extremely variable depending on the species, seasonal trend and latitude. This period varies from 2 weeks to 8 months, reaching 2 years in some arctic species. The pupal stage is very short, lasting 2–10 days. The pupae float

on the water surface and breathe with the prothoracic respiratory horns. Most species overwinter as fourth-instar larvae, although, cases of summer diapause are also documented. During the spring, the wintering larvae pupate and give rise to the first generation. Each generation can last from 2 weeks to over a year depending on the species, latitude and climatic conditions. Generally, the emerging *Culicoides* adults, stay close to the breeding sites and form swarms to mate. After mating, females disperse in search of a food source.

The multivoltine species complete two or more generations per year while univoltine produce only one generation per year. The presence and abundance of adults varies greatly throughout the year and each species shows a typical seasonal trend with characteristic peaks of abundance.

Ecology

Adult ceratopogonids have a wide range of feeding habits. Both sexes regularly feed on plant sugar, as nectar of flowers. Only the females of the genera *Austroconops*, *Culicoides*, *Leptoconops* and those belonging to the subgenus *Lasiohelea* of the genus *Forcipomyia* are hematophagous by sucking vertebrate blood. The blood meal is required to have protein reserves for egg maturation. Some species are autogenous by absorbing at the larval stage enough nutrients to bring the first egg deposition to maturity. However, these species require a blood meal to complete additional gonotrophic cycles. The autogeny is documented for several species belonging to the genera *Culicoides* (e.g., *Culicoides circumscriptus*, *Culicoides impunctatus*), *Leptoconops* (e.g., *Leptoconops kerteszi*, *Leptoconops carteri*), *Forcipomyia* (e.g., *Forcipomyia inornatipennis*, *Forcipomyia squamipennis*) and *Dasyhelea*, in which all species appear to be autogenous for the first cycle.

Culicoides females feed on vertebrate hosts, primarily on mammals, birds, and reptiles. While several species are host-specific, showing a preference for a group of animals, others are generalist and feed on a wide range of animals, depending on host availability. There are also species that exploit other insects, such as the *Culicoides anophelis* which feeds on the ingested blood from the abdomen of the *Anopheles* mosquitoes.

Visual stimuli and olfactory systems are involved in midge-host interactions by highly sensitive receptors located on the antennae and maxillary palps. Lactic acid, acetone, butanone, 1-octen-3-ol, CO₂ are the most important semiochemicals involved in host-location and host-selection. *Culicoides* are telmophages that use toothed tip of mandibles and maxillae to lacerate the skin causing the leakage of small drops of blood which are sucked through the pharyngeal pump. Following the bite the diuresis process begins, determining the concentration of the ingested blood. Females remain hidden in the vegetation or in other protected environments until eggs maturation.

Mating of *Culicoides* usually takes place in flight, with males swarming adjacent to hosts on which females are feeding or in proximity of moist environments where females lay the eggs, depending on the species. Swarming and mating are modulated by sex pheromones. Most species mate only once and the sperm stored in the spermathecae is sufficient to fertilize all eggs laid throughout midge life.

Most *Culicoides* species have crepuscular and nocturnal activity while some species (e.g., *Culicoides phlebotomus*, *Culicoides kingi*, *Culicoides paraensis*) as well as *Leptoconops* are more active during the day. Among the first, some species show a bimodal pattern of flight activity with peaks during sunrise and sunset (e.g., *Culicoides brunnicans*, *Culicoides impunctatus*), while others are more active only at dawn time (e.g., *Culicoides debilipalpis*) or dusk time (e.g., *Culicoides furens*, *Culicoides obsoletus*).

Several climatic variables affect flight activity of adult *Culicoides*, especially temperature, light intensity, wind speed, relative humidity, rainfall, barometric pressure, and lunar cycles. Among them temperature and wind are of fundamental importance. Temperatures out of range steadily restrict the activity of midges. In this regard, adults of *C. variipennis* and *C. brevitarsis* became inactive at temperatures lower than 10 °C and 18 °C, respectively. Conversely, temperatures higher than 32 °C affect the flight activity of *C. variipennis* while *Culicoides barbosai* is much less active with temperature greater than 24 °C.

After emergence, *Culicoides* adults remain mainly in proximity of breeding sites, flying for short distance to seek shelters, hosts, females to mate, or other oviposition sites. Because of their small size, midges are not very strong fliers and the flight are limited when wind speed over 2–2.5 m/s. Generally, all activities are suppressed at wind speeds higher than 2.7 m/s for *C. furens* in the Caribbean regions or 3 m/s for *C. imicola* in Africa. In the last decades, several studies are carried out to estimate the short-range dispersal and evaluate the mean distance travelled by *Culicoides* adults within and between farms. One of the most important methods used is the Mark-Release-Recapture (MRR) technique which estimates the ratio of recaptured specimens to the total of marked individuals released in a defined area. The mean flight distance for females is relatively similar between species. Adults of *Culicoides mississippiensis* were recaptured after 24 h between 2 and 2.5 km from the release point. *Culicoides mohave* midges were found 12 h post release at 1.2 km. The maximum distance travelled by marked specimens of *C. variipennis* and *Obsoletus* group was 1.93 km and 1.75 km, respectively. The mean flight distance for males is estimated in less than half of that for females. It is of relevant epidemiological importance the fact that midges can passively be carried by the wind over considerable distances, even over 700 km, explaining the introduction and spread of *Culicoides*-borne diseases in new free areas.

The larvae of the Ceratopogonidae present a cutaneous respiration and develop in aquatic or semi-aquatic environments. *Leptoconops* larvae are found in sandy soils and along the beaches and marshes near the coasts while larvae of the genus *Dasyhelea* can develop in bums, but also in the roots of umbrella plants. The larvae of *Culicoides* genus develop in a wide range of moist environments rich in decaying organic matter (Fig. 11): marshy soils, low margins of brackish ponds, streams and rivers, puddles, irrigation pipe leaks, leaking watering troughs, marshes, peat bogs, tree holes with standing water, rotting wood, cacti and fungi, waterlogged pastures, animal manure, mangroves. In muddy environment, the vertical distribution of the larvae is very homogeneous and they are rarely found below 5–7 cm depth. Many habitats can simultaneously host larvae belonging to different genera. As regards the diet, the larvae of family Ceratopogonidae are primarily predators of eggs and larvae of chironomids, mosquitoes, other midges, nematodes, annelids and protozoa. *Culicoides* larvae can have a phytophagous, zoophagous and saprophic regime. Many species are generalists and omnivorous feeding on algae, diatoms, fungi, bacteria, and organic substances. The ecology of

Fig. 11 Some typical *Culicoides* larval habitats. (A) Permanent puddle, (B) temporary puddle, (C) mud close to leaking water trough, (D) manure heap, (E) dung puddle, (F) marsh. Photo credit: Cipriano Foxi.

Culicoides larvae is better known for salt marsh species, some of which are important vector of viruses, and tree-hole species while for most species feeding habits remain unknown.

Medical importance

Culicoides biting midges with their bites cause, in some regions, annoyance and discomfort to humans, especially in outdoor recreation and work activities. The bites can be painful causing a slight temporary burning and mild swelling lasting up to a few hours. Secondary infection may occur if bite is scratched vigorously. In this regards, *C. impunctatus* is particularly important, being responsible for 70–95% of the attacks on humans in some European countries. This biting midge causes serious damage to human

activities, preventing the development of tourism during the summer days. In the United States, some species, such as *C. furens*, *C. mississippiensis*, *C. melleus* and *C. barbosai*, represent the most troublesome midges biting humans, especially in coastal zones.

Culicoides can transmit viruses and filarial nematodes to humans (Table 1). Although several viruses have been isolated from *Culicoides* biting midges, it is only a few viruses that seriously affect humans. The most important is Oropouche virus, which belongs to the family Peribunyaviridae. Oropouche virus is responsible for Oropouche Fever, a widespread disease in tropical areas of Central and South America, especially in Trinidad and Tobago, Perú, Colombia and Brazil. This virus produces acute flu-like symptoms with fever, headaches, vomiting and muscular and joint pains. Although it is generally nonfatal, the symptoms can last up to 2 weeks and in rare cases evolves into meningo-encephalitis. Oropouche virus is maintained in nature in a complex cycle involving both an urban and a sylvatic cycle. In the urban cycle humans are the sole vertebrate host, while in the sylvatic cycle, mammals and birds represent the natural reservoir hosts. The predominant vector is *Culicoides paraensis*, but some mosquitoes belonging to the genera *Aedes*, *Culex* and *Coquillettidia* can also contribute to the virus transmission, with low efficiency of transmission.

While no protozoan blood parasites are transmitted to man by *Culicoides*, some species of this hematophagous flies are vectors of filarial nematodes of the genus *Mansonella*. In particular, three species are pathogenic to man, *M. ozzardi*, *M. streptocerca* and *M. perstans*, causing mansonellosis. Infestations evolve asymptotically or, rarely, with mild clinical symptoms. Humans are the only known vertebrate hosts for *M. ozzardi*, while others primates are involved in the cycle of *M. streptocerca* and *M. perstans*. *Mansonella ozzardi* is widely present in South America and Caribbean regions, where *C. furens* and *C. phlebotomus* are the main vectors. Other species that have been found to support the development of the parasite are *C. barbosai* and *Leptoconops bequaerti*. Also blackflies of the genus *Simulium* appears to be competent vectors for *M. ozzardi*. *Mansonella perstans* occurs mainly in Central and West Africa where *C. austeni*, *C. inornatipennis*, *C. grahamii* and some species belonging to *C. milnei* group are the main vector species. This nematode was introduced to Central and South America but the vectors have not yet been identified. *Mansonella streptocerca* is restricted to the tropical Africa, where *C. grahamii* is considered its main vector.

Veterinary importance

In domestic and wild animals, *Culicoides* can transmit almost 60 viruses, 40 protozoa species and 24 filarial nematodes species (Table 1). In recent years, also a bacterium has been detected in adults of *C. brevitarsis*, thus hypothesizing its possible role as a vector. In some areas, midges can occur in abundant numbers and their persistent bites can lead to allergic reactions in the animal skin, including the so-called “Sweet itch” or “Queensland itch” in horses.

Certainly, biting midges are well known as vectors of a number of viruses causing economically important livestock diseases. Among them, Bluetongue virus, African horse sickness virus, Epizootic hemorrhagic disease of deer virus and Schmallenberg virus are considered to be some of the most important, as causing mortality, abortions, sterility, reduced milk yields, and other serious losses in the affected animals. These arboviruses have a defined geographical distribution correlated with their vector species and hosts. However, especially in recent decades, disease incursions into areas previously immune to outbreaks have been observed. This expansion can mainly be related to intense international trades and more favorable climatic conditions for the vectors in these new areas. An explanatory example is the spreading of Bluetongue in previous unaffected European countries and the discovery of Schmallenberg virus, which has never been detected in Europe before.

Bluetongue virus was widespread in the world and has been found before the 2000s affecting ruminants in Australia, Middle/Far East in Asia, Africa and Americas, restricted to the geographical areas included between 40° and 50° North latitude and to the 20° and 30° South latitude (Kundlacz et al., 2019). Sporadic incursion for BTV has been observed for restricted period in the European countries of the Mediterranean Basin until 1998. This distribution radically changed in the period 1998–2005, when five different BTV serotypes, namely 1, 2, 4, 9, and 16, were diagnosed in the countries of Mediterranean Basin, with Greece and Italy being the first involved countries. After 2006, BTV incursion started in Northern European countries, with severe consequences determined by the serotype 8 (Saegerman et al., 2008). While the incursion of BTV in the European Mediterranean countries was connected with Northern African countries, after 2006 the circulation of BTV in the Nord Europe was of unknown origin. Globally, 9 BTV conventional serotypes, namely 1, 2, 3, 4, 6, 8, 9, 11, and 16, have been characterized in numerous outbreaks in Europe, so far. The factors that could have influenced this northward spread of the Bluetongue are the well-known climatic changes, the northward expansion of *C. imicola* and the vector competence of autochthonous European *Culicoides* species. In the last years a significant increase in temperatures has been observed in Europe (Purse et al., 2005). Undoubtedly, the temperature greatly influences the *Culicoides* life cycle and the BTV transmission cycle. Warmer temperatures increase development, activity and survival rate of *Culicoides*, viral replication rates and could enhance vectorial capacity of European *Culicoides* species.

African horse sickness

African horse sickness (AHS) is a viral insect-borne disease affecting equine species caused by AHS virus (AHSV), which belongs to the Orbivirus genus. Severe and often lethal clinical signs are observed most frequently in horse than in mule and African donkey (Mellor and Hamblin, 2004). Zebra species are considered asymptomatic reservoir playing an important role in the epidemiology of AHSV in Africa, (Becker et al., 2018). With regards to other species, in dogs AHSV can be fatal after eating contaminated

Table 1 Pathogens transmitted by *Culicoides* biting midges.

Tinaroo	<i>C. brevitarsis</i>	Antibodies detected in cattle, buffalo, sheep, goats	Australia
Vesicular stomatitis-New Jersey	<i>C. variipennis</i> , <i>C. stellifer</i> , <i>Culicoides</i> (<i>Selfia</i>) spp.	Horses, cattle, swine, humans	North, Central and South America
Wallal	<i>C. dycei</i> , <i>C. marksii</i> , <i>Culicoides</i> spp.	Marsupials (antibodies also detected in various vertebrates)	Australia
Warrego	<i>C. dycei</i> , <i>C. marksii</i> , <i>C. actoni</i> , <i>Culicoides</i> spp.	Antibodies detected in various vertebrates	Australia
Weldona	<i>Culicoides</i> spp.	Birds	North America
Wongorr	<i>C. pallidothorax</i> (also mosquitoes)	Antibodies detected in humans and other vertebrates	Australia

^aPathogens in each group are listed in alphabetical order.

horsemeat (Van Rensburg et al., 1981) and camels are also reported as susceptible, however both species should be considered accidental hosts (Mellor and Hamblin, 2004).

AHS is endemic in Africa with the most affected countries being in the Sub-Saharan territory, particularly in South Africa. In this country, epidemic waves appear around every 10–15 years associated with climate conditions connected to different phase of El Niño (Baylis et al., 1999). However, outbreaks of AHS has been also reported outside of Africa causing relevant costs to the equine husbandry. AHS was diagnosed in 1944 in Israel, between 1959 and 1966 in Turkey, Middle East, and South West Asia (Howell, 1960; Dennis et al., 2019). More recently, in the period 1987–91 the disease was reported in Morocco, Portugal and Spain (Lubroth, 1988), thus raising concerns on the risk that could be constituted by the international movements of competition horses (Herholz et al., 2008). In addition, on the basis of the unexpected wide spreading in Europe in the early 2000s of bluetongue virus, which is closely related to AHSV, it remains the significant risk for the introduction the AHS to the European countries.

It has been suggested that the first sites of virus replication are the regional lymphoid tissues. After a first viremia, a subsequent invasion in several organs is observed, with a particular tropism to lung, spleen and heart (Mellor and Hamblin, 2004). By using electron microscopy AHSV has been localized in the endothelial cells (Laegreid et al., 1992). Further studies, based on immunohistochemistry and in situ hybridization analysis, have demonstrated that AHSV antigen mostly accumulates in the endothelial cells of the micro vessels, in the infiltrating macrophages and circulating monocytes of the lung, heart and spleen (Brown et al., 1994; Clift and Penrith, 2010), thus suggesting that sampling from these organs is the most appropriate for diagnostic purposes. In addition, after experimental intranasal inoculation, a neurotropic strain of AHSV was immunohistochemically found associated with damaged neuron and astrocytes in the gray matter of the brain (Clift and Penrith, 2010).

The viremic phase in AHS is very short compared to other related arbovirosis such as Bluetongue, ranging 4–8 days post-infection, (Coetzer and Erasmus, 1994). In the blood of the infected animal, AHSV is associated to the red cells component, probably engulfed in the cellular membrane, miming what was demonstrated for BTV in cattle.

The clinical outcomes of AHSV infection in horses is very variable, ranging from subclinical to fatally severe, with the mortality rate estimated around 95%–100% (Clift and Penrith, 2010). Clinical aspects of the disease have been summed up in four different forms, namely horse sickness fever, mixed, cardiac and pulmonary (Mellor and Hamblin, 2004). The pulmonary form is commonly considered to be the most fatal acute form while the mixed form is the most common. The mortality rate in the pulmonary form achieves the 100% in many outbreaks. The fever form is the mildest which only displays a transitory rise of fever. However the different clinical courses of the disease are not easy to distinguish in practical conditions (Scacchia et al., 2015). Frequent clinical signs include marked depression, dyspnea, coughing, as well as oedema of the head, neck and orbital fosses (Fig. 12). Petechial

Fig. 12 Horse affected by AHS. Edema of the orbital fosses (A), pulmonary edema (B) and gelatinous edema of the inter-muscular fascia (C). Photo credit: Massimo Scacchia, Istituto Zooprofilattico Sperimentale dell'Abruzzo e del Molise.

haemorrhages are frequently found in the conjunctival mucosae and in the ventral surface of the tongue. At the necroscopy, gross changes are hydropericardium, ascite in the dominal and pleuric cavity, oedema of the subcutaneous tissues and of the muscular fascea (Fig. 12).

Bluetongue disease

Bluetongue (BT) is an arbovirosis affecting ruminants and caused by Bluetongue virus (BTV), which belongs to the family Reoviridae, genus Orbivirus. BTV genome consists in 10 segments of linear double stranded RNA (Seg-1 to Seg-10), encoding 7 structural proteins (VP1-Vp7) and five non-structural proteins (NS1 to NS4 and S10-ORF2) involved in viral replication, morphogenesis and assembly processes. The intermediate capsid protein layer VP7 expresses group antigens common to all BTV strains, VP2 and VP5 outer capsid proteins are involved in the virus binding and entering into the mammalian and, probably, insect vector cells (Mertens and Diprose, 2004; Lourenco and Roy, 2011; Jacquot et al., 2019). Sequence variability of VP2 forms the basis for grouping/classifying BTV into different serotypes (Patel and Roy, 2014).

Based on variations in their nucleotide sequences genome segments, two major geographic BTV groups are defined and named as western or eastern topotypes. The western topotype includes viruses given source from Africa and the Americas, the eastern includes viruses from the Middle East, India, China and Australia (Mertens et al., 1987; Gould and Pritchard, 1990; Pritchard et al., 1995, 2004; Maan et al., 2008).

Up to now there are 24 conventional BTV serotypes able to cause BT. Recently, plus novel serotypes in goats have been identified as atypical because the infected animals are generally asymptomatic and the virus can be transmitted by direct contact (Maan et al., 2011; Zientara et al., 2014; Schulz et al., 2016; Sun et al., 2016; Savini et al., 2017; Marcacci et al., 2018).

The clinical outcomes of BTV infection are significantly different among the species. In sheep they can be severe with high rate of mortality (MacLachlan et al., 2008), whereas in cattle, goats and wild ruminants symptoms they usually are mild, if not, completely absents. By using controlled experimental conditions it was demonstrated that the species of the host and the single isolates of the BTV serotype play a key role in modulating the clinical aspects (Caporale et al., 2014). In clinically susceptible ruminants, most common symptoms are different grades of fever, conjunctivitis, hyperaemia of the periorbital areas, nasal discharge, anorexia, lameness, prostration, and subcutaneous oedema in the inter-mandibular space, hemorrhagic-necrotic erosions on the dorsal mucosal surface of the tongue, which in the severe cases exhibited a bluish staining (Fig. 13). In experimental BTV infection the body temperature increases at 6 days post intra-dermal inoculation together with other early clinical (Puggioni et al., 2018). One the morpho-pathological feature, which results in the clinical presentation of BTV infection, is the localization of the virus in the

Fig. 13 Ram affected by BT. Representative photos showing characteristic clinical signs, including inter-mandibular edema (A), conjunctivitis (B), mucopurulent nasal discharge (C), erythema with ulcerations in the buccal mucosae (D), coronitis (E), erythema of the scrotum and inguinal skin areas (F). endothelial cell of vessel (MacLachlan et al., 2008). Indeed, BTV is detected in sheep, during 24 h after experimental infection, particularly associated with the endothelial cells of the lymphatic, rather than hematic vessels, in the dermis of the skin close to the inoculation sites. Within 24 h after infection, BTV is also found in the sinus of the draining lymph nodes of the inoculation point, inside the macrophages and the endothelial cells and in the cortical follicles associated to the B lymphocytes. Later, from 3 to 11 days post infection, replication of BTV is mostly observed by immunohistological staining in the endothelial cells of the smaller vessel in numerous organs, particularly skin, lung, lymphoid tissues nodes far from the side of inoculation, and testicles (Melzi et al., 2016; Puggioni et al., 2018). At 15 days after inoculum BTV is not detected in the endothelial cells by immunohistochemistry (Puggioni et al., 2018). In the blood of the host, BTV is associated with platelets, but considering the short lifespan of these cells, it is mostly engulfed into the cell membrane invagination of erythrocytes, remaining infectious despite the presence of neutralizing antibodies (Brewer and MacLachlan, 1992; Parsonson and McColl, 1995). The viremic status has been considered, by using PCR assay or virus isolation in culture cells, long lasting until several weeks in cow (Singer et al., 2001; MacLachlan, 2004).

Serological diagnosis of BTV infection is carried out using enzyme-linked immunosorbent assay (ELISA) tests that detect anti-VP7 antibodies in the serum and milk of animals infected with BTV (Gumm and Newman, 1982; Hamblin, 2004). Serum neutralisation test is the only serological method that is able to identify and quantify BTV serotype antibodies specific and determine viral serotype responsible for the infection. In order to confirm clinical cases, to establish uninfected animals before moving and for surveillance purposes, OIE recommends the use of a real-time RT-PCR (RT-PCRNS3) assay (OIE, 2019). The method real-time RT-PCRNS3 described by Hofmann et al. (2008) is suitable to identify the serogroup by retro-transcription and amplification of a region of segment 10 of the viral RNA, coding for a non-structural NS3 protein. Real time RT-PCR targeting in Seg-2 coding for a least conserved outer virion capsid protein (VP2) recognizes the specific BTV serotype (Huismans and Erasmus, 1981; Shaw et al., 2013).

Epizootic haemorrhagic disease

Epizootic haemorrhagic disease (EHD) is an insect-born disease caused by a virus (EHDV) belonging to the genus Orbivirus and affecting wild and domestic ruminant species. The disease was first recognized during the 50s years (Shope et al., 1960) in white tailed deer (*Odocoileus virginianus*). By molecular and serological data based on the reactions between the structural proteins V2 and V7 and the specific neutralizing antibodies, seven different serotypes of EHDV have been recognized and conventionally accepted (Anthony et al., 2009; King et al., 2012).

Whole genome sequencing has demonstrated that some EHD isolates were reassortant between different serotypes, suggesting that these seven serotypes are not stable and multiple strains could come out annually in different outbreaks (Allison et al., 2010; Wang et al., 2019). These serotypes have different geographical distribution, EHDV-1, EHDV-2 and EHDV-6 are endemic in USA (Allison et al., 2010), while EHDV-6, previously indicated as EHDV-318, and EHDV-2 are found in the Arabic peninsula (Mohammed et al., 1996; Savini et al., 2011). Moreover, EHDV serotypes 2, 3 and 4 have been identified in the African countries (Savini et al., 2011), whereas EHDV serotypes 1, 2, 5, and 7 have been characterized in Australian sentinel cattle (Maan et al., 2010; Savini et al., 2011). A particular EHDV-2 strain, named Ibaraki, which is phylogenetically considered to be as an Asian topotype (Maan et al., 2010), was isolated in Japan causing severe clinical disease in cattle (Ohashi et al., 1999). Beyond Japan, others EHDV outbreaks in cattle have been reported in the Mediterranean basin due to the EHD serotypes 6 and 7 (Yadin et al., 2008; Temizel et al., 2009).

Clinical signs following EHDV infection have been mostly observed in white tailed deer and much less in cattle, in which clinical disease remains sporadically associated to EHDV-2, EHDV-6, EHDV-7 and Ibaraki virus. In cattle cases, clinical signs included serous-purulent nasal discharge, scialorrea, muzzle redness, and tongue swelling with cyanosis and erosions (Yadin et al., 2008; Temizel et al., 2009). A wide range of wild ruminants is found to be susceptible to EHDV, including captive yaks (*Bos grunniens*) (Van Campen et al., 2013), bighorn sheep (*Ovis canadensis*) (Clark et al., 1985) in USA, and gray brocket deer (*Mazama gouazoubira*) in Brazil (Favero et al., 2013). In these outbreaks, clinical manifestations of disease were reported, however the symptomatic disease is a rare event in these wild ruminants, despite that seroprevalence in the endemic areas is usually found relatively high.

In white tailed deer, peculiar clinical signs during the course of the EHD are fever, redness of the orbital areas, perineum and ear pinna, hyperemia of the conjunctiva, facial oedema, erythema of buccal mucosae with ulcerations and bleeding (Fig. 14).

In white tailed deer experimentally inoculated with EHDV-2 and EHDV-7 serotypes, clinical signs started between 4 and 5 days post-infection (Quist et al., 1997; Ruder et al., 2012). In these experiments, lesions were minimal to severe and included petechial or ecchymotic haemorrhages in the pulmonary artery and peritoneal serosa and necrosis secondary to bacterial infections. In addition, pulmonary edema was observed with different individual severity. The length of the viremic phase was different among the infected animals and ranged 4–56 days post infection (Quist et al., 1997) by using the EHDV-2 serotype or between 3 and 39 days after inoculum of EHDV-7 (Ruder et al., 2012). The haematochemical examinations showed leukopenia, lymphopenia, hypoproteinaemia and diminished platelet count (Ruder et al., 2012). In cattle, experimentally infected with EHDV-6 serotype, high levels of viral RNA were demonstrated in the blood, although they displayed very mild, if any, clinical signs, thus suggesting that this specie can be a reservoir of the virus (Breard et al., 2013; Batten et al., 2011). During the autopsy of experimental EHDV inoculated cattle, virus RNA was isolated from various tissues by RT-qPCR, such as spleen, liver, skin, kidney, and lymph-nodes (Breard et al., 2013). These clinical and pathological findings, together with many other field observations, suggest a manifested species and individual variability of the clinical outcomes in deer and cattle with EHD, as observed in sheep affected by BT (Caporale et al., 2014).

Fig. 14 Deer affected by EHD. Mild clinical signs after experimental infection. Redness of the orbital areas, ear pinna, muzzle, and peri-orbital skin. Photo credit: Juergen Richt, Kansas State University and William Wilson, USDA-ARS.

Currently, there are no experimental studies aimed to define the kinetic of EHDV infection in the host body. However, on the basis of the clinical-pathological patterns which have been observed so far in field and experimental conditions, EHDV infection share many aspects with better studied Orbivirus infections, such as BT in ruminants. Indeed, as in BTV, EHDV early localizes in the endothelium of the smaller vessels causing disseminated intravascular coagulation (MacLachlan et al., 2009). Considering the long viremic phase in deer and cattle (Quist et al., 1997; Batten et al., 2011; Breard et al., 2013), it is also conceivable that this virus remains strictly adherent to the cell membrane of the erythrocytes, thus surviving despite the presence of neutralizing antibodies, as observed in bovine bluetongue (MacLachlan et al., 2009).

Schmallenberg disease

Schmallenberg disease (SBD) is an arbovirosis causing abortion, congenital malformations in newborn lambs, calves and kids, whilst in the adult ruminants, mild clinical signs such as drop of milk production, hyperthermia, and diarrhea are occasionally reported (Hoffmann et al., 2012; Lievaart-Peterson et al., 2012). The etiological agent is the recent discovered Schmallenberg virus (SBV). By metagenomic analysis, SBV was isolated in the blood of cows hold in a dairy farm located in the village of Schmallenberg (North Rhine-Westphalia, Germany), at the end of the summer 2011 (Hoffmann et al., 2012).

SBD has been described in many other European countries including Italy, Spain, Belgium, France, United Kingdom, with a total of 29 countries being involved (European Food Safety Authority (EFSA), 2012; Afonso et al., 2014). As consequence of this epidemic wave, SBD caused productive performance losses in the affected farms and a negative impact on the well-being of the farmer dealing with this new emerging disease (Häsler et al., 2015; Pythian and Glover, 2019).

Specific antibodies against SBV or viraemia are reported in numerous wild ruminant species in natural and experimental conditions, including alpacas, water buffalo, elk, bison, deer and chamois (European Food Safety Authority (EFSA), 2014). However, the failure to observe clinical signs and the low seroprevalence suggests that the role of the wild animals in the epidemiology of SBV requires further investigations (Collins et al., 2019). So far, the data available for domestic dog are conflicting. While in one dog showing neurological signs, SBV genome was found in the cerebellum (Sailleau et al., 2013), in a serological survey no dogs seropositive for SBV were found (Garigliany et al., 2013). No antibodies or viraemia has been found in human exposed to SBV in the affected farm (European Food Safety Authority (EFSA), 2012).

The source of SBV remains unknown. This gap is firstly due to the little knowledge on the phylogeny of SBV and of the other closely related Simbu serogroup virus, which is widespread in other continents (Collins et al., 2019). Interestingly, antibodies against SBV were found in 56.6% of dairy cattle sampled in Ethiopia during the period September 2011–12 (Sibhat et al., 2018), as well as, between 2012 and 2014, SBV seropositivity rates for cattle and sheep were found of 91.2% and 65.4%, respectively, in Nigeria (Oluwayelu et al., 2018).

Taken together these reports demonstrated that SBV was circulating even in Africa, soon after its earlier appearance in Europe. Nowadays, circulation of SBV in the ruminant population could be considered worldwide (Rasekh et al., 2018; Zhai et al., 2018).

SBV viraemia is short lasting both in sheep and calves and RNA is detected until 5–6 days post inoculum (Hoffmann et al., 2012; Poskin et al., 2014). In calves experimentally infected, neutralizing antibodies in blood were detected firstly at 21 days after inoculum (Hoffmann et al., 2012) and remained present until 63 days (Wernike et al., 2013). Seroprevalence of SBV in the affected bovine herd can be very high, reaching 75% of rate (King et al., 2015), while in sheep and goat are 43.8% and 58.7%, respectively (Helmer et al., 2015). The presence of neutralizing antibodies may be not sufficient to prevent re-infection, as infected sheep with

neutralizing antibodies had viraemia (Jones et al., 2019). However, in a previous experimental study SBV seropositive calves, which were re-challenged, did not develop testable viraemia (Wernike et al., 2013).

Considering that diffusion of SBV is strictly related to the seasonality of the *Culicoides* vectors, the infection occurs in the summer and in the autumn, with the outcomes on the fetus being evident at the end of gestation period. In this regard, a long surveillance period in France revealed that congenital malformations occurred mostly during the months of January-February in cattle and November-December in ewes (Cache et al., 2018). However, some SBV infection may occur even in the winter (Cache et al., 2018).

The characteristic signs of SBD are the malformations of the offspring, which are the outcomes of the infection of the dams at determined stage of gestation, the transplacental crossing capacity of the virus and the susceptibility of the embryo tissues to the virus. An overview of the studies based on challenging pregnant ruminants with SBV suggested that this virus has a limited capacity to cause malformations in the foetus (Collins et al., 2019). Depending on the breeding strategy applied in the different farms, the within flock sheep prevalence of malformed stillborn was estimated between 3% and 19% (Dei Giudici et al., 2013).

For understanding the pathogenesis of SBV, data from experimental study on Akabane (AKA), a closely related Simbu serogroup virus, has been used (Konno et al., 1982). It is assumed that, the outcomes of AKA virus (AKAv) infection on embryos are strictly determined by the gestation period at which dams are infected. In pregnant cow, AKAv is able to affect the embryo after the first month of gestation, with the critical period ranging from the 3rd to 6th month, causing fetal malformation in the central nervous system and skeletal muscle (Konno et al., 1982; Kirkland et al., 1988). By challenging pregnant sheep with intravenous inoculations, AKAv was demonstrated after 24 h in the placenta, however, only in sheep at 46–53 days of gestation fetus malformation occurred (Parsonson et al., 1988).

In naturally infected pregnant cows, the embryo seems to be susceptible for the SBV between 47 and 162 days of age (Wernike et al., 2014). The gross morphological examination of the SBV malformed stillborn lambs, kids and calves mostly found hydrocephalus, cerebellar hypoplasia and spinal cord hypoplasia in the central nervous system as well as brachygnathia inferior, curvature of the vertebral spine (kyphosis, scoliosis and torticollis) and arthrogryposis in the musculoskeletal system (Fig. 15). Histologically, moderate focal of lymphocytic meningo-encephalomyelitis are observed in some malformed brains with the lymphocytes T being the most represented inflammatory cells (Herder et al., 2012, 2013). Interestingly, a significantly higher occurrence of malformations interests only one of the twin lamb pregnancy.

Control

Culicoides control programs are generally implemented to reduce biting nuisance of livestock and/or humans and arbovirus transmission. Control measures can be applied against both larvae and adults. In the framework of Integrated Pest/Vector Management (IPM/IVM) and One Health criteria, habitat manipulation and larvicidal treatments with chemical and/or biorational insecticides have been the mostly used strategies against *Culicoides* larvae. Habitat management, such as alteration and/or removal and drainage of breeding sites, could be useful for reducing larval development sites and *Culicoides* larval density, particularly, for those species that live in specific and well know breeding habitats. An essential factor that affects the effectiveness of a larval control is the perfect knowledge of the immature habitats. *Culicoides* midges lay eggs in a wide range of moist environments with the larvae being generally semi-aquatic and susceptible to desiccation. However, removing the breeding sites for reduce the abundance of *C. sonorensis*, the North American Bluetongue virus vector, from a farm, did not result in a reduction of vector population compared with an untreated farm (Mayo et al., 2014). Habitat alteration covering dung heaps and mechanical disrupting cowpats have a negligible effect in reducing population density for European species such as *C. scoticus*, *C. chiopterus* and *C. dewulfi* (Lühken et al., 2014a,b).

Several studies have been carried out to evaluate the efficacy of larvicidal application on larval habitats, mainly on species responsible for biting nuisance. A significant larvicidal efficacy of organophosphates, pyrethroids, organochlorines and Insect Growth Regulators was reported against *C. furens*, *C. melleus*, *C. mississippiensis*, *C. sonorensis*, and *C. circumscriptus* in laboratory and field trials. More recent biorational larvicides showed a promising efficacy against biting midges. These active products include plant extracts, like neem-based products (Mulla and Su, 1999; Benelli et al., 2017), entomopathogenic fungi, namely *Metarhizium anisopliae*, *Beauveria bassiana*, and *Paecilomyces fumosoroseus* (Ansari et al., 2010, 2011; Nicholas and McCorkell, 2014; Narladkar et al., 2015), and mermithid nematodes such as *Heleidomeris* species (Mullens et al., 2008). The efficacy of bacterial agents *Bacillus thuringiensis* var. *israelensis* and *Bacillus sphaericus*, widely employed in the field control of mosquitoes, were tested mainly in laboratory trials. Several studies showed *B. t. israelensis* to be ineffective against field collected *Culicoides* larvae (Kelson et al., 1980; Larget and De Barjiac, 1981). By contrast, in another study *B. t. israelensis* and *Bacillus sphaericus* showed a lethal effect on Indian *Culicoides* species (Narladkar et al., 2006). A significant biocidal activity was also exhibited by *Brevibacillus laterosporus* in laboratory and field trials against some European *Culicoides* species (Foxi et al., 2019).

The IPM/IVM of *Culicoides* adults can be implemented with physical and/or chemical methods. Physical control strategies include housing livestock in stables during seasonal activity period of *Culicoides* midges to reduce biting activity. Nets on the windows are useful to limit the entry of midges inside the shelters. For a more successful strategy, these window nets can be treated with insecticides or repellents. Chemical control of *Culicoides* adults can be achieved by treating animal body with insecticides or repellents, mainly pyrethroids, with pour-on or dip-wash formulations. However, the real efficacy of this method in reducing biting rate has not been proved (Carpenter et al., 2008). Although the broad scale treatments on the whole farm area have not reduced the

Fig. 15 Stillborn lambs affected by SB. Malformations include arthrogryposis and torticollis (A), brachygnathia (B), spider-like arthrogryposis (C), hydrocephalus (D), skull malformation (E), macroscopic and histological feature of the spinal cord hypoplasia compared with a control (F). Photo credit: Davide Pintus, Istituto Zooprofilattico Sperimentale della Sardegna.

number of *Culicoides* adults (Satta et al., 2004), the treatments restricted to the walls and roofs of animal shelters combined with larval treatments on breeding sites has determined a significant reduction of *Culicoides* adult density (Meloni et al., 2018).

As a conclusion, the control of *Culicoides* is not easy feasible and should be conducted according to the guidelines of IPM/IVM, combining the different techniques available. Indeed, a single strategy as a stand-alone technique usually show limited effects in reducing the abundance of *Culicoides* vector species and consequently on pathogens transmission (Carpenter et al., 2008; European Food Safety Authority (EFSA), 2008; Mullens et al., 2015; Pfannenstiel et al., 2015; Harrup et al., 2016; Benelli et al., 2017).

Introduction

The small size of flies in the family Simuliidae, with wingspans of 3–15 mm, belies the magnitude of their importance in medical, veterinary, and economic sectors of society. The nearly 200 vernacular names applied to these widespread insects (Davies, 2006) attest to their global significance. Numbering about 2330 species worldwide (Adler, 2020), or roughly 1.5% of all species of flies, they are most often referred to as “black flies” (or “blackflies”).

Driven by the quest for vertebrate blood to mature their eggs, female blackflies are responsible for withering attacks on humans, domesticated animals, and wildlife, often with significant economic losses and transmission of the agents of disease. Yet, only about 10–20% of the world’s species actually hold status as pests or vectors of disease agents of consequence to humans and their animals (Adler and McCreadie, 2018). Simuliid-borne human diseases include onchocerciasis and mansonellosis, the former debilitating and the latter mild. The most prominent simuliid-borne animal diseases include avian trypanosomiasis and leucocytozoonosis, onchocerciasis, and vesicular stomatitis.

Adult blackflies are compact insects characterized by an arched thorax—inspiring the common name “buffalo gnats”—anteriorly concentrated wing veins, and short beadlike or conical antennae (Fig. 1). But, not all blackflies are black. Many are gray, orange, iridescent, or patterned. Male blackflies have large, contiguous compound eyes (holoptic), whereas females have smaller, separated eyes (dichoptic). Species of the family can be notoriously difficult to identify, a problem compounded by the high frequency of cryptic species that show little to no structural differentiation and must be identified by chromosomal or molecular criteria (Adler et al., 2010; Adler and Crosskey, 2015).

The immature stages are confined to freshwater streams and rivers where the eggs (Fig. 2) are deposited. Upon hatching larvae lead a largely sedentary life as filter-feeders attached to in-stream substrates (Fig. 3). Pupation takes place in a silken cocoon spun from the enormous larval silk glands; the cocoon anchors the pupa to an object in the flow (Fig. 4). The adults are terrestrial and diurnal. Only the females feed on blood, whereas both sexes take water and sugars, such as floral nectar and insect honeydew (Stanfield and Hunter, 2010).

Biology and ecology

Blackflies occupy two profoundly different environments—the aquatic and the terrestrial. The dichotomy sets up a paradox whereby the immature stages are ecosystem benefactors but the adults, more specifically the females, are often in direct conflict with humans and their enterprises. Society is, therefore, faced with safeguarding its citizens and economic interests while conserving the ecological benefits of blackflies.

Blackflies are found everywhere that freshwater flows, including desert oases and remote oceanic islands. They are remarkably common insects. In any given area of the world, they are typically found in 90% or more of flowing water habitats, from the tiniest streams to the largest rivers. Although they are generally associated with clean waters, some species are quite pollution-tolerant. Mountainous areas of the globe, which offer a wide range of habitats along an elevation gradient, typically have the greatest number of species. Blackflies are often the most abundant macroinvertebrates in running water, reaching densities of 1 million larvae per square meter in extreme cases (Wotton, 1988).

The larvae attach to objects in the current, such as stones, trailing vegetation, and refuse (e.g., plastic), by enmeshing tiny abdominal hooks in a silk pad spun from the large silk glands. About 30 highly specialized species are phoretic, attaching to, and developing on, larval mayflies (Ephemeroptera) in Africa and Central Asia and to freshwater crabs and prawns in tropical Africa (Crosskey, 1990). Larval life concludes with spinning a silk cocoon in which molting to the pupa occurs. The compact pupa, with its conspicuous pair of respiratory organs (gills), is adapted for gas exchange in water or in air if decreasing water levels strand it.

The larvae of all but 1% of the world’s species are filter feeders, capturing fine particulate matter (0.09–350 µm in diameter) with their labral fans and processing it into fecal pellets rich in carbon, nitrogen, and bacterial films, which become available as food to

Fig. 2 Eggs of a blackfly, *Simulium vittatum*. Photo by Jena Johnson.

other aquatic organisms (Malmqvist et al., 2004). Fecal production by larval black flies can reach astonishing levels—429 metric tons of dry mass passing a river site per day—prompting researchers to refer to black flies as “ecosystem engineers” (Wotton et al., 1998; Malmqvist et al., 2001). Larvae also feed by scraping adherent material from the substrate; the 25 species that lack labral fans do so exclusively. Some species, especially those living in nutrient-poor streams, ingest small prey items. Larvae disperse or relocate by moving inchworm fashion or drifting on silk lifelines that they spin. Peak drifting of larval black flies occurs around dusk.

The egg stage can last a few days to years, depending on environmental conditions such as temperature and water availability. Some species undergo an obligatory egg diapause through the winter or the summer. Larvae can develop in as few as 4 days to as long as 6–9 months, depending largely on temperature. They typically pass through six or seven instars, although more if parasitized or starved. The pupal stage usually lasts a few days to a few weeks. The entire life cycle from egg to adult can be completed in 2 weeks or less, with some species in tropical environments completing as many as 15 or more generations per year. Univoltine species, those that complete a single generation annually, are associated with northern environments and high elevations. Adults emerge from the pupa in a partial covering of air and fly to a nearby location to tan and harden the body and wings.

The essentials of adult life are completed within a typical lifespan of a month or less: mating, sugar feeding, and for the females, blood feeding and egg laying. Mating takes place shortly after emergence, usually when males form swarms into which entering females are intercepted. These swarms typically form over landmarks, such as waterfalls, tips of tree branches, and bare ground. Less frequently, males and females locate one another and mate on the ground near the emergence site. About 15 species are parthenogenetic; males do not exist.

About 97.5% of all species have mouthparts fitted for cutting animal tissue. The other 2.5% of species, all in far-northern or extreme high-elevation environments, have mouthparts incapable of cutting animal tissue; they mature their eggs without blood (obligate autogeny). In cooler environments, larvae with high-quality diets produce females that can mature their eggs without benefit of a blood meal for the first cycle of egg production but require blood for subsequent egg batches (facultative autogeny). Most species of blackflies, however, require blood for all cycles of egg maturation (anautogeny). Multiple gonotrophic cycles of blood feeding and oviposition are possible and are prerequisites for parasite acquisition and transmission. Females of some species,

particularly certain vectors in the *Simulium damnosum* complex, can disperse up to 500 km before a blood meal, although dispersal distances of fewer than 20 km are typical for most species (Crosskey, 1990). The female flies locate their blood hosts—exclusively birds and mammals—by a series of cues, such as host color, size, shape, and odor, especially carbon dioxide (Sutcliffe, 1986), which provides an effective method of sampling and trapping female flies.

Female flies deposit their eggs directly into the water during flight, or they lay them in strings and masses while walking on wetted surfaces or vegetation trailing in the current. Communal egg laying on substrates is mediated in some species by pheromones emitted from the freshly deposited eggs (McCall et al., 1997). The number of eggs matured in one ovarian cycle varies from 30 to more than 800, depending on the species (Crosskey, 1990).

Although the blood hosts of most species of blackflies are unknown, the general feeding habits can be inferred from the structure of the claws. Females that feed on mammals have curved claws, with or without a small basal tooth, whereas females that feed on birds have curved talons with a variably sized thumblike lobe that aids purchase as the flies move through feathers. Thus, roughly 51% of all bloodsucking species of blackflies feed predominantly on mammals and the other 49% on birds. At times, however, some species feed indiscriminately on birds and mammals, regardless of claw structure. Mammalophilic blackflies, including anthropophilic species, typically do not venture into enclosures to acquire blood meals. At least some ornithophilic species, however, frequently enter avian nest cavities and other enclosures (e.g., bird houses). Host tissue is cut by the serrated mandibles, which operate as micro-scissors to produce a pool of blood that is imbibed (Sutcliffe and McIver, 1984). Blackflies are determined feeders, typically completing a blood meal on a single host animal, acquiring about 2 μ l or more of blood per meal. The numerous molecules in simuliid saliva play a variety of roles: localized anesthesia, prevention of clotting, modulation of the host immune response, inhibition of platelet aggregation, enhanced vasodilation, and direction of microfilarial parasites to the feeding site (Cupp and Cupp, 1997; Stallings et al., 2002).

The various life-history attributes of blackflies, such as requirements for flowing water, egg diapause, aerial swarming for mate finding, and blood feeding, can complicate sustained laboratory colonization. Few species, consequently, have been colonized for more than one generation. The most prominent exception is the abundant North American species *Simulium vittatum*, which has been in perpetual laboratory colonization for nearly 40 years without introduction of wild material since its inception (Gray and Noblet, 2014).

Medical and veterinary importance

The negative effects of blackflies on humans, their animals, and wildlife can be categorized as nuisance problems, reactions to bites, and disease. These categories are not mutually exclusive; individual species of blackflies can be both pests and vectors.

The effects of blackflies on outdoor activities, such as agriculture, forestry, and tourism, are legendary. But only about 10% of species worldwide are anthropophilic, and no species feeds exclusively on humans. Human variation in the attraction of black flies depends on a number of factors, most importantly the individual's production rate of carbon dioxide (Schofield and Sutcliffe, 1996). Swarms of flies crawling on the body and entering the eyes and other openings, whether biting or not, can be a terrific nuisance. A single persistent blackfly darting about the face and into the eyes can be a nuisance to a golf enthusiast, and one bite can cause an eye to swell shut. The bite is often manifested by a small, purplish, subcutaneous hemorrhagic spot that may or may not ooze blood, depending on the species of blackfly and the components of its saliva. Localized inflammation, swelling, and intense itching can occur. Dozens, hundreds, or thousands of bites can cause blackfly fever, a response to the saliva of the flies, resulting in nausea, fever, headaches, and swollen lymph nodes. Greater fly densities at a host prompt increased feeding rates, at least in some species, suggesting an "invitation effect" (McCall and Lemoh, 1997). More than 6700 bites per person per day have been recorded in Brazil's northern Amazon Basin (Shelley et al., 2010), and more than 13,000 in the Democratic Republic of the Congo (Makenga Bof et al., 2019). In severe cases, allergic reactions and hospitalizations can occur (Gudgel and Grauer, 1954). No authenticated human deaths have been attributed to blackflies, historical anecdotes notwithstanding.

Domesticated animals are frequent targets of blackflies. The attacks are often directed at unfeathered areas of birds, such as around the eyes, or thinly haired areas of mammals, such as the belly and face and in the ears. Reactions of domesticated animals under siege can be severe and include weight loss, reduced egg and milk production, delayed pregnancies and abortions, malnutrition of young animals, unruly behavior and stampedes, dermatitis, stress-related diseases such as pneumonia, and death (Fredeen, 1977). A handful of species, notably *Cnephia pecuarum*, *Simulium colombaschense*, and *S. vampirum*, are responsible for a large number of animal deaths from direct blood-feeding attacks (Adler et al., 2004, 2016). The worst recorded outbreak of blackflies occurred along Romania's Danube River in 1923 when more than 22,000 animals died (Ciurea and Dinulescu, 1924). A debilitating, often fatal, condition known as "simuliotoxicosis" involves acute toxemia and anaphylactic shock resulting from introduction of excessive salivary components during blood feeding (Adler and McCreadie, 2018). The distinction between death from simuliotoxicosis versus exsanguination is not always clear.

The effects of blackflies on wildlife are less conspicuous because of the difficulty of observing host animals in the wild. Nonetheless, many cases of attacks have been documented, and deaths are not uncommon, particularly among nestling songbirds and raptors (Adler et al., 2004). These attacks are especially worrisome when the fitness of endangered wildlife is severely reduced (Adler et al., 2019).

An abundance of flies that can cause pest problems generally occurs by one of two pathways: developing in the majority of flowing-water habitats in an area (habitat generalists), or developing in the world's largest rivers (habitat specialization) (Adler, 2016). Many of the worst pest species breed in large rivers, some of which produce nearly a billion flies per kilometer of riverbed per day (Amrine, 1982; Adler et al., 2016).

Epidemiology: Humans

Two human diseases are simuliid-borne, and several additional human diseases or syndromes have been associated with, but not definitively linked to, blackflies. The two bona fide simuliid-borne human diseases are onchocerciasis (river blindness) and

mansonellosis (or mansonelliasis). The filarial nematodes *Onchocerca volvulus* and *Mansonella ozzardi* are the causal agents that provoke the two diseases, respectively. At least 26 species of blackflies serve as vectors of *O. volvulus* and at least five as vectors of *M. ozzardi* (Adler and McCreddie, 2018). Other than humans, no animal reservoir is known for either of the two filarial species.

All investigated blackflies responsible for transmitting these filarial worms are complexes of cryptic species with differential capacities as vectors (Post et al., 2007; Adler et al., 2010, 2017). The most important vectors involved in onchocerciasis are in the African *Simulium damnosum* complex, which includes about 13 species with vector competency; the majority of species in the *S. damnosum* complex are not vectors. Different strains of *O. volvulus* are associated with different members of the *S. damnosum* complex, forming parasite–vector complexes, such as the forest and savanna complexes in West Africa (Basáñez et al., 2009; Cheke and Gams, 2013). Only about one-quarter of the 28 members of the *S. damnosum* complex in East Africa are anthropophilic (Krueger, 2006). Removal of alternative hosts of the *S. damnosum* complex, such as cattle, in onchocerciasis foci can increase anthropophily and, hence, the risk of human onchocerciasis (Krüger et al., 2005). The *S. neavei* group, which includes the species obligatorily phoretic on freshwater crustaceans, and *S. albivirgulatum* are additional vectors of *O. volvulus* in East Africa. The *S. guianense* complex is a major vector in the few remaining New World foci.

According to the Global Burden of Disease Study in 2017, an estimated 20.9 million people are infected with *O. volvulus*, of which 14.6 million have skin disease and 1.15 million have vision loss (Makenga Bof et al., 2019). More than 99% of the cases are in 31 countries of Africa's central belt, with scattered foci in Yemen and the New World. The disease, which was introduced to the New World, presumably with the slave trade, at one time was endemic in two countries of Central America (Guatemala and Mexico) and four of South America (Brazil, Colombia, Ecuador, and Venezuela). Onchocerciasis has been eliminated from all New World onchocerciasis foci except a few that straddle the Brazil–Venezuela Amazonian region (WHO, 2016). In Africa, some of the greatest success in conquering onchocerciasis has been achieved in Sudan and Uganda.

Female blackflies acquire microfilariae (275–300 µm long) from humans during blood feeding. The peritrophic matrix in the fly's midgut and, in some species, the toothed cibarial armature, serve as barriers to microfilariae, thereby reducing injury to the vector. The tiny worms make their way from the fly's midgut to its flight muscles where they transform to first-stage larvae (L1) and then second-stage larvae (L2). Another molt produces the infective third-stage larvae (L3) that travel to the head and mouthparts of the flies where they are ready for delivery to a human, the definitive host, during blood feeding. The infective larvae can be transmitted to another human when the fly is about 7–10 days old, corresponding to when the fly would take a third blood meal. Once in humans, the third-stage larvae molt to incipient adult worms that grow and, within a year to a year and a half, begin reproducing. Adult male and female worms become encapsulated in relatively benign subcutaneous nodules (Fig. 5) where they mate. Nodules typically form where the infective larvae enter the body, which is determined by where the particular vector species blood feed, for example, on the lower body in Africa, but on the head and shoulders in Latin America. Each long, slender female worm (35–70 cm long) subsequently releases millions of microfilariae over the next 14 years of its potential lifespan. Temperature determines when parasites can become infective and when vectors can transmit them, suggesting that climate change could have profound effects on transmission dynamics (Cheke et al., 2015).

The familiar name “river blindness” or, in the New World, “Robles disease” masks the range of manifestations of the disease. The release of enormous numbers of microfilariae by adult female worms, and the movements of the tiny worms through the dermis

Fig. 5 Nodule encapsulating adult filarial worms of *Onchocerca volvulus*, and rough skin typical of onchocerciasis in Nigeria. Photo by Roger Crosskey.

and the inflammatory responses when they die, can cause insufferable itching with various sequelae, including secondary infections, loss of sleep, and suicide. Social stigma can be associated with the disease. Chronic heavy infections with microfilariae also cause changes to the skin (Fig. 6): lesions, depigmentation (leopard skin), loss of elasticity (elephant knees and, combined with lymphatic challenges, hanging groin), fibrosis, dry wrinkling (lizard skin), and swollen dark areas (sowda in Yemen, Fig. 7; Abdul-Ghani et al., 2016). Two additional skin conditions are known from Central America, involving rashes on the face (erisipela de la costa) and on the torso and arms (mal morado) (Vargas, 1974).

Visual impairment by the microfilariae, particularly the inflammatory response when they die, and co-involvement of their obligate endosymbiotic *Wolbachia* bacteria (Tamarozzi et al., 2011) is the most serious consequence of infection, especially when it leads to total, irreversible blindness. Ocular issues, in addition to blindness, include, inter alia, corneal inflammation and opacities, retinal hemorrhages, and secondary glaucoma. Frequency of blindness is greatest in the West African savanna, whereas it is minimal or absent in areas such as the East African highlands, Latin America, and Yemen.

Mansonellosis is caused by the simuliid-borne filarial nematode *Mansonella ozzardi* (Shelley and Coscarón, 2001); additional species of *Mansonella* are transmitted by ceratopogonid midges (*Culicoides*). Blackflies, especially certain members of the *S. amazonicum* species group, in northern Argentina, Brazil, Colombia, Guyana, Panama, and Venezuela transmit the filarial worms. Infection rates in human populations can be high, generally 20–47%, and the disease is spreading into uninfected areas (Adami et al., 2014). The life cycle of the worms is comparable to that of *O. volvulus*. The microfilariae typically circulate in the blood of humans, and sometimes can be found in the skin. Ocular pathology and dermal issues are not associated with the disease, and it has historically been considered of little concern. Some recent evaluations, however, indicate associated headaches, joint pains, and other complications (Adami et al., 2014; Ta-Tang et al., 2018). Like *O. volvulus*, *M. ozzardi* is associated with symbiotic *Wolbachia* bacteria (Casiraghi et al., 2001). Of the vector-borne diseases of humans, mansonellosis remains one of the most neglected (Mediannikov and Ranque, 2018).

Additional, albeit rare examples, of parasite transmission to humans by blackflies are known. A total of 37 cases of zoonotic onchocerciasis involving at least 11 species of *Onchocerca* have been reported (Saeung et al., 2020). Female blackflies seeking a blood meal can serve as hosts for transmitting the eggs of the New World human bot fly (*Dermatobia hominis*), which hatch upon contacting the vertebrate host (Guimarães and Papavero, 1966). This simuliid–bot dynamic is probably underreported.

Several additional diseases and syndromes of humans—fogo selvagem (pemphigus foliaceus), thrombocytopenia, and nodding syndrome—have been associated with blackflies, although the connections remain nebulous. Fogo selvagem is a rare blistering cutaneous disease that has been associated with the presence of blackflies in rural areas of Brazil (Aoki et al., 2004). Thrombocytopenia, a condition of lowered platelets, has been associated with the bites of blackflies, also in Brazil (Pinheiro et al., 1974). Nodding syndrome is a neurological condition of unknown etiology, which involves epileptic seizures, head dropping, and staring. It primarily affects children in parts of South Sudan, Tanzania, and Uganda, especially in areas associated with onchocerciasis, and can progressively worsen to include death (Johnson et al., 2017; Abd-Elfarg and Boele van Hensbroek, 2019). Effective treatment is not available. Human pathogens detected in or on blackflies, but without compelling evidence of field transmission, include hepatitis B virus (Chanteau et al., 1993) and *Mycobacterium leprae*, the causal agent of leprosy (de Souza-Araujo, 1961).

Epidemiology: Domesticated animals and wildlife

Four general diseases of domesticated animals and wildlife are simuliid-borne: avian trypanosomiasis, filariasis (e.g., bovine onchocerciasis and canine ocular onchocerciasis), leucocytozoonosis, and vesicular stomatitis.

Simuliid-borne avian trypanosomiasis is caused by protozoans in the genus *Trypanosoma*. The most common species of *Trypanosoma* associated with blackflies is *T. avium*, which infects numerous species of vectors and hosts (Bennett, 1961). Pathways of infection include contamination of the bite by fecal droplets from blackflies and consumption of other birds or blackflies that are infected (Votýpka and Svobodová, 2004). Infections are typically subclinical.

A total of 32 species and one subspecies of *Onchocerca* have been reported as parasites of mammals worldwide (Uni et al., 2020), although the presence of cryptic species underestimates this figure (Verocai et al., 2018). Blackflies (and ceratopogonid midges) are vectors. Among the more prominent hosts are cattle, with blackflies the vectors of *O. dukei*, *O. gutturosa*, *O. lienalis*, and *O. ochengi*. The microfilariae typically concentrate in different body regions, for instance those of *O. lienalis* in the umbilical region and those of *O. gutturosa* in the skin of the neck and back. The effects on bovid hosts are typically minor or subclinical, although the quality of hides and milk might be reduced (Beytut et al., 2005). *Onchocerca volvulus*, the causal agent of human onchocerciasis, is hypothesized to have been derived from an ancestral onchocercid parasite of bovids during their domestication (Lefoulon et al., 2017). Nonbovid hosts of simuliid-borne onchocercids include canids, cervids, and suids. Canine ocular onchocerciasis caused by *O. lupi*, with occasional infections in felids and humans, is an emerging ophthalmic disease; simuliids have been implicated as vectors in some cases (Hassan et al., 2015). In cervids, the worms are found in subcutaneous connective tissues, especially of the legs, giving rise to the vernacular names “footworms” and “legworms”; heavy infections can cause hoof damage (Verocai et al., 2012). A few species of simuliid-borne *Onchocerca* infect the subcutaneous tissues in the feet of wild boars and warthogs (Uni et al., 2001). Like *O. volvulus* of humans, simuliid-borne onchocercids of domesticated and wild animals are hosts of *Wolbachia* bacteria (Uni et al., 2020).

Additional filarial worms transmitted by blackflies include *Splendidofilaria fallisensis*, a parasite of ducks (Anderson, 1968) and *Dirofilaria ursi* a parasite of black bears (Addison, 1980), both of which infect the subcutaneous tissues. Tiny nematodes in the family Robertdollfusidae have been recovered from African blackflies and are possibly transmitted to wildlife (Bain and Renz, 1993). Given the diversity of filarial worms in wildlife, simuliid transmission of additional parasitic species can be expected.

Leucocytozoonosis is a malaria-like disease of birds caused by protozoans of the genus *Leucocytozoon* (O’Roke, 1934). The vectors are blackflies, such as *S. anatinum* and *S. rugglesi* of *Leucocytozoon simondi* in ducks and geese and *S. meridionale* and *S. slossonae* of *Leucocytozoon smithi* in turkeys. A wealth of new *Leucocytozoon* species and host–vector relationships continue to be resolved with molecular techniques (Murdock et al., 2015). When gametocytes are acquired from an avian host during a blood meal, a complex life cycle ensues, with the parasite undergoing asexual and sexual development in the blackfly over the next several days. The *Leucocytozoon* parasite is transmitted, as sporozoites, to another bird during a subsequent blood meal, where it undergoes asexual development and gametocyte production (Figs. 8 and 9). Although clinical signs of leucocytozoonosis in wild birds are often negligible, the disease can be pernicious among domesticated ducks, geese, and turkeys; hence, it is sometimes colloquially called “gnat fever,” “duck malaria,” or “turkey malaria.” The disease in domesticated birds can manifest with a variety of clinical signs, such as an enlarged spleen and liver, anemia, anorexia, and weakened immunity, sometimes leading to mortality. The devastating effects of leucocytozoonosis in North America’s poultry industry occurred largely before the 1980s when birds, such as turkeys, were raised outdoors where they were readily available to host-seeking blackflies (Adler et al., 2004). The effects of *Leucocytozoon* infections in

wild birds are difficult to separate from the direct effects of blood feeding. Both factors, however, probably have greater consequences when birds experience low food availability and other environmental stressors (Hunter et al., 1997).

Various serotypes of vesicular stomatitis virus (VSV) infect wildlife and livestock, especially cattle and horses, causing blistering epithelial lesions often followed by lameness and weight loss. Animals usually recover but major economic losses can result during outbreaks. Some states and countries restrict movement of animals from areas with cases of VSV. Multiple transmission routes include blood feeding by arthropods, such as blackflies (e.g., *Simulium vittatum*), which are epizootic vectors of the New Jersey serotype (Mead et al., 2009). The relative contribution of blackflies to outbreaks is, however, unknown.

Additional animal pathogens have been detected in blackflies, but the ability of the flies to transmit most of them in the field is unknown. These pathogens include eastern equine encephalitis virus (Anderson et al., 1961); snowshoe hare virus (Sommerman, 1977); *Francisella tularensis*, the causal agent of tularemia (Yakuba, 1963); *Zelonia australiensis*, a trypanosomatid protozoan (Barratt et al., 2017); and a trematode (Lewis and Wright, 1962). Various levels of transmission, whether biological or mechanical, have been found for the myxoma virus in domestic rabbits (Mykutowycz, 1957), Whataroa virus in mice (Austin, 1967), Venezuelan equine encephalitis virus from laboratory guinea pigs to mice (Homan et al., 1985), and *F. tularensis* in laboratory guinea pigs (Philip and Jellison, 1986). The role of simuliids as vectors in nature is considered minimal for these pathogens, with the exception of myxoma virus in rabbits. Chlamydia infections in sheep and Rift Valley fever might be simuliid-borne in South Africa (Palmer, 1995). All of these pathogen–vector relationships, and others yet to be investigated, deserve more serious attention.

Prevention and control

Defense against blackflies is an age-old effort, practiced at both personal and community levels. Yet, only in the past century did it begin developing into a science of control and prevention, with annual budgets of some programs exceeding US\$5 million annually (Adler et al., 2004).

Early realization that blackflies were concentrated in streams and rivers typically made larvae, rather than adults, the preferred targets for control. Although physical control, such as managing water levels or removing attachment substrates for the larvae, has been applied with varying levels of success, most efforts historically emphasized chemical control. Applications of kerosene, oils,

and other hydrocarbons to streams initiated the chemical era of blackfly population suppression. DDT followed in the early 1940s into the early 1970s. Subsequently, methoxychlor and temephos were popular chemicals used in larval control. However, resistance in the flies and the effects on nontarget organisms eventually spelled the reduction or elimination of chemical applications to running water.

A remarkable number of organisms—more than 190 nonbacterial species—live in larval blackflies in some form of symbiosis, mostly in parasitic relationships (McCreadie et al., 2011). The value of biological control of blackflies was recognized more than a century ago, and intense efforts were focused, especially in the 1970s, on the potential benefits of mermithid nematodes, fungi, and other natural enemies (Laird, 1981; Adler et al., 2004). The discovery of the bacterium *Bacillus thuringiensis* variety *israelensis* (*Bti*) in larval mosquitoes in 1976 initiated the modern era of simuliid control. The bacterium, specifically the endotoxins it produces during sporulation, has proved highly effective in area-wide management programs for blackflies, with little negative effect seen to date on nontarget organisms. Applications are made either by hand (Fig. 10) or by aircraft. *Bti* is now the gold standard of larval control worldwide (Gray and Fusco, 2017). The diverse microbiome of blackflies offers potential opportunities for future means of control (Tang et al., 2012).

On a more personalized level, smoke, especially from cigars and smoldering materials (smudges), has been used to ward off adult flies. All imaginable repellents have been applied to humans and their animals—greases, tars, plant oils, mud, skin softeners, and the like. Nearly all of these materials have fallen out of favor, although applications of Vaseline inside the ears of livestock, particularly horses, in small-scale operations can provide reliable protection. Various sprays, dusts, pour-ons, and ear tags, as well as sheltering, have been used to protect livestock. Birds in nest boxes can be protected by surrounding the holes with adhesives. For people, head nets and light-colored clothing fitted to exclude crawling flies can be effective, albeit uncomfortable. The most effective modern repellents for personal use typically contain N, N-diethyl-meta-toluamide (DEET) or icaridin (picaridin).

A special set of control efforts has involved the herculean battle against human onchocerciasis. The World Health Organization's Onchocerciasis Control Programme (OCP) in West Africa, followed by the African Programme for Onchocerciasis Control (APOC), operated effectively, primarily by larviciding (Fig. 11), from the early 1970s through 2015 (Davies, 1994; Coffeng et al., 2013). With the close of APOC, the World Health Organization established the Expanded Special Project for the Elimination of Neglected Tropical Diseases to coordinate technical support for five diseases, including onchocerciasis (Colebunders et al., 2018).

A new era in the fight against onchocerciasis came in 1987 with the pledge of Merck & Co. to donate ivermectin tablets (Mectizan®) as long as needed, and the efforts of other organizations (e.g., The Carter Center and the Task Force for Global Health) to mass distribute the tablets. A similar effort in Latin America, the Onchocerciasis Elimination Program for the Americas, began operations in 1993 (Blanks et al., 1998), with great success. Ivermectin is highly effective against the microfilariae, but does not kill the adult worms; doses every 6 to 12 months are, therefore, needed for the long life of the adult female worms. The latest development in the onchocerciasis battle springs from the discovery of *Wolbachia* bacteria in the filarial worms, which provides a means of killing the adult worms with antibiotics, especially doxycycline (Bouchery et al., 2013; Taylor et al., 2014). In some areas, the elimination of onchocerciasis would still leave a significant pest problem where biting rates remain high, as in the Democratic Republic of the Congo. A combination of ivermectin and doxycycline, combined with vector control, offers tremendous hope for the eventual elimination of onchocerciasis and any associated pest problems.

Continued success in the control and management of blackflies will depend on increased ability to identify target species, detect genetic changes in parasites and vectors, monitor changes in pest and vector populations brought on by habitat alteration and

climate change, and maintain and develop an arsenal of environmentally safe suppression tools. Monitoring for resistance to the current tools, particularly *Bti*, ivermectin, and antibiotics aimed at *Wolbachia*, will be essential.

Acknowledgments

I thank Jena A. Johnson, Abdul Samad, and Gediminas Valkiunas for permission to use their photographs; Mohammed A. K. Mahdy and Rashad Abdul-Ghani for acquiring the photo from Yemen; Margaret Crosskey for providing the photos by her late husband, Roger Crosskey; and A. G. Wheeler, Jr., for providing comments on an earlier draft of the text.

Introduction

The family Tabanidae is a well-known worldwide distributed group of hematophagous Diptera of great economic importance. Compared to other hematophagous insects, they have received only a little attention (Baldacchino et al., 2014a). Tabanids are differently named according to the taxonomic group or geographical region. Commonly they are referred to as horse flies (also written as horseflies or horse-flies) which is the name generally applied to the Tabaninae species (except the tribe Haematopini), deer flies (the term used preferentially for species of the genus *Chrysops*) or clegs (sometimes as glegs or clags; the name used for the genus *Haematopota*). On top of that, several other names are commonly used, e.g., gad-flies (from the word “gad” meaning a spike), stouts, hippo-flies, dun-flies, breeze flies (this name is used particularly in North America) or March flies (in Australia). They feed on many vertebrate hosts, including humans. Their medical and veterinary importance resides mainly in the painful bite and their role of efficient biological and mechanical vectors of various human and animal disease agents including viruses, bacteria, and parasites.

Medical and veterinary importance

A direct effect of tabanids on their hosts

Tabanids have a painful bite and persistent biting behavior, which makes them nuisance pests for humans and animals, mainly livestock, in particular large-bodied species such as horses and cattle (Fig. 1). Wildlife is also affected, mainly large mammalian species; however, *Chrysops* and other smaller species feed (occasionally) also on birds (e.g., ravens, crows, ducks) and reptiles (e.g., turtles). Their noisy flight combined with a large size produce also visual stress when they approach and land on the host. Large accumulations of flies do occur in some areas, and with their painful bite tabanids can be pests of both livestock and humans. Areas with abundant tabanid populations are negatively affected due to the impact on tourism, outdoor activities (e.g., trekking, fishing, camping, and swimming), and also farming. In fact, horse flies have directly resulted in decreases in the weight gain of cattle of 0.1–1 kg/day (Baldacchino et al., 2014a).

Except for the painful bite (Fig. 2), as tabanids are large insects, the blood loss associated with their feeding is also important and depends on the horse fly species and size: ranging from 20 to 25 μ L for many *Chrysops* species to almost 700 μ L per bite of *Tabanus atratus*. The host blood loss continues after the bite by oozing (Fig. 3) and can be aggravated by opportunistic blood-feeding flies (Fig. 4). Bite sites can be used by myiasis causing flies for ovi/larviposition. Often the bites result in local skin reactions such as nodules. High densities are also responsible for decreased milk production and weight loss mainly in cattle, due to impaired feeding. Salivary components found in tabanids correspond entirely with their feeding strategy of engorging a large blood-meal within a few minutes. They are exophilic/exophagic (outdoor blood-feeding) and telmophagous (feeding from a pool of blood caused by tissue laceration) and take blood meals during the day. The saliva of tabanids exhibits strong anticoagulant and vasodilatory activities, together with a broad repertoire of platelet aggregation inhibitors, and immunoregulatory peptides

(Volfová et al., 2016), it has also a toxic effect (Baldacchino et al., 2014a) and may induce allergic reactions in sensitive individuals (Bircher, 2005).

Vectorial role

Tabanids are important vectors of human and animal pathogens, acting both as biological and mechanical transmitters for a variety of pathogenic organisms. Over the past few decades, the epidemiological relevance of tabanids as mechanical vectors has been focused on the increasing incidence of some veterinary important diseases, above all equine infectious anemia, bovine besnoitiosis, and livestock trypanosomoses. Of the biologically transmitted human pathogens, the filarial nematode *Loa loa* has recently re-emerged as a disease agent of public health importance, because of its negative impact on the control of onchocerciasis and

Fig. 3 The bleeding of an attacked horse caused by the bite of the tabanids (*Hybomitra* sp.) will soon attract other insects interested in its blood. Photo: Jana Bulantová.

Fig. 4 Opportunistic flies feeding on the blood leaking from the site of the tabanid (*Haematopota* sp.) bite. Photo: Andrei D. Mihalca.

lymphatic filariasis in areas of co-endemicity. Additionally, tabanids are involved in the phoretic transmission of the human botfly *Dermatobia hominis* (Oestridae) in the Neotropical region.

Biological transmission

Tabanids are demonstrated as biological vectors for three groups of parasitic organisms: filarial nematodes, trypanosomes, and apicomplexans (Baldacchino et al., 2014a).

The filarial nematode *Loa loa*, also known as the Tropical eye worm is responsible for the disease known as loiasis, occurring mainly in rainforests of Central and West Africa (Kelly-Hope et al., 2017). The adults live in the subcutaneous connective tissue of humans, producing edematous swellings on the body known as Calabar swellings. Occasionally, the parasites can migrate under the conjunctiva of the eye (Anderson, 2000). Two species of the genus *Chrysops* are the main incriminated vectors of *L. loa* in humans: *Chrysops silacea* and *Chrysops dimidiata*. Both species are canopy dwellers of African equatorial rainforests (Kelly-Hope et al., 2017). Although the loiasis is usually not severe, high levels of microfilaremia are associated with serious symptoms and death in patients using nematocidal drugs (i.e., ivermectin or diethylcarbamazine) for other diseases such as lymphatic filariases or onchocercoses (Kelly-Hope et al., 2017). In tabanids, *Loa loa* develop from the L1 stage (microfilariae) to L3 in the fat body tissue of the body, head, and thorax. From the fat body, they migrate to the mouthpart and emerge through the proboscis during feeding. The development takes from 10 to 12 days (Anderson, 2000). Two other species, *Chrysops zahrai* and *Chrysops distinctipennis*, have lesser importance but still can act as biological vectors of human loiasis. All above mentioned *Chrysops* species plus *Chrysops centurionis* and *Chrysops langi* could be involved in the transmission of simian loiasis in several monkeys and great apes (*Cercopithecus mona*, *Cercopithecus nictitans*, *Mandrillus leucophaeus*, chimpanzee, and both species of gorillas) and various experimental attempts of interspecific transmission of *Loa* between humans and other primates using *Chrysops* tabanids were done (see Anderson, 2000; Votýpka et al., 2020).

Tabanids have been also demonstrated as biological vectors for other filarial nematodes. The larvae of *Pelecitus roemeri* (formerly *Dirofilaria roemeri*), a filarial parasite in the subcutaneous and intermuscular tissue of the knee region of several species of Australian marsupials, develop in several tabanid species belonging to the genera *Dasybasis*, *Mesomyia*, *Scaptia*, and *Tabanus* (Anderson, 2000). The intermediate hosts for *Elaeophora schneideri*, a filarial parasitic nematode of the carotid arteries and their branches in sheep and mule deer, *Odocoileus hemionus* in western North America, are also various species of the tabanid genera *Hybomitra* and *Tabanus* (Anderson, 2000).

Various tabanids act as biological vectors for the non-pathogenic kinetoplastid, *Trypanosoma theileri* species complex (Fig. 5) which includes several trypanosome species hardly distinguishable due to the lack of discriminating morphological characters (however, diseases associated with this pathogen in cattle were sporadically reported). Trypanosomes belonging to this group have been isolated from different domestic and wild bovine, ovine, and cervids in Europe, Africa, Asia, and the Americas. The principal vectors of the *T. theileri* group are considered tabanid flies (however, *T. melophagium*, also belonging to the *T. theileri* species complex, is transmitted exclusively by sheep keds). After ingestion of blood with trypomastigotes from infected hosts, the parasites multiply through a cyclopropagative stercorarian development in the posterior part of the digestive tract of various horse fly species (e.g., *Haematopota pluvialis*, *Hybomitra micans*, *Tabanus autumnalis*, and *T. bromius*—Fig. 6) (Böse et al., 1987).

Tabanid flies have been implicated as the vectors for the North American species of turtle malarial parasites, *Haemocystidium* (*Simondia*) *metchnikovi* (formerly described as *Haemamoeba metchnikovi*) belonging to the genus *Plasmodium* sensu lato (Galen et al., 2018). The infective sporozoites have been identified in the salivary glands of the tabanid *Chrysops callidus* in Michigan, USA (DeGiusti et al., 1973); hence, this tabanid species is incriminated as an intermediate host and biological vector of this hemosporean parasite in turtles. Tabanids have been assumed to be the vectors for all members of the clade, but this should be validated because their role in the transmission of South American, Middle Eastern, or other chelonophilic taxa has not been confirmed.

Mechanical transmission

The mechanical transmission does not require a biological interaction between the pathogen and the arthropod vector; the infectious disease agent does not replicate and/or develop (e.g., does not undergo physiologic changes) in/on the vector. Due to their feeding behavior with multiple bites on different hosts, tabanids are particularly important as mechanical vectors for viruses, bacteria, and parasites. Their painful bite results in the flies often being disturbed while feeding, but they are persistent and will commonly move directly to another animal to recommence feeding. Because of this, and the rather “spongy” nature of the labella,

Fig. 5 *Trypanosoma theileri* s.l. in a blood smear of an asymptomatic cow sampled in Romania. Photo: Andrei D. Mihalca.

Fig. 6 *Tabanus bromius* (A) and *T. autumnalis* (B). Photo: David Modrý (A); Jana Bulantová (B).

which can hold up to a nanoliter of blood, they are excellent mechanical vectors. Their role as mechanical vectors has been extensively reviewed by Krinsky (1976) and Baldacchino et al. (2014a). One of the most important viruses transmitted by tabanids (genera *Tabanus*, *Hybomitra*, and *Chrysops*) is the Equine infectious anemia virus which is responsible for a severe disease of horses. Other viruses mechanically transmitted by tabanids in animals (mainly livestock) include the bovine leukosis virus, the bovine viral diarrhea virus, hog cholera virus, vesicular stomatitis virus, and rinderpest virus. Among bacteria, the mechanical transmission has been demonstrated for *Anaplasma marginale*, *Francisella tularensis* (this zoonotic disease is widespread throughout the Holarctic and is transmitted by a variety of agents, but in the USA the tabanid *Chrysops discalis* is a major vector), *Bacillus anthracis*, *Clostridium chauvoei*, *Pasteurella multocida*, *Listeria monocytogenes*, *Erysipelothrix rhusiopathiae*, and *Ehrlichia risticii*. Among protozoa, natural or experimental proof of transmission by tabanids has been shown for *Besnoitia besnoiti*, *Trypanosoma evansi*, *T. vivax*, *T. equiperdum*, *T. simiae*, *T. brucei* complex, and *T. congolense* (a detailed review is available in Baldacchino et al., 2014a).

Additionally, several other viruses (California encephalitis virus, western equine encephalitis virus, tick-borne encephalitis virus, influenza virus) and bacteria (*Borrelia burgdorferi* sensu lato, *Coxiella burnetii*) have been isolated from tabanids, but no proof of transmission was confirmed (Baldacchino et al., 2014a).

Phoretic transmission

Tabanids, among other dipterans, are used by the neotropical human botfly, *D. hominis*, to phoretically spread their eggs (Baldacchino et al., 2014a). Females of *D. hominis* use as a primary egg dispersal technique the oviposition directly on the body of other insects. As summarized by Catts (1982), *D. hominis* females will choose as ovicarriers insects which fulfill the following characteristics: (1) are zoophilic; (2) are diurnal; (3) have moderate size; and (4) moderate activity. The eggs are glued with a water-insoluble secretion to the abdomen of the carrier insects, with the operculum directed posteriorly. A carrier insect can transport even more than 35 eggs (Catts, 1982). Although mosquitoes seem to be the preferred transport hosts for *D. hominis* eggs, several other insect groups have been involved such as Anthomyiidae, Calliphoridae, Fanniidae, Muscidae, Sarcophagidae, Simuliidae, and Tabanidae. Among tabanids, species of genera *Chrysops* and *Tabanus* are included here (Baldacchino et al., 2014a).

Biology and ecology

Taxonomy and diversity

Tabanidae Latreille, 1802 is a family of the order Diptera (Linnaeus, 1758), suborder Brachycera (Macquart, 1834), infraorder Tabanomorpha (Hennig, 1948), and superfamily Tabanoidea (Latreille, 1802). They are a cosmopolitan (absent from some islands, e.g., Greenland, Iceland, and Hawaii), gathering almost 4400 described valid species in 137 genera worldwide (Pape et al., 2011; Pape and Thompson, 2020). This diversity eclipses any other hematophagous insect group, for instance biting midges, Ceratopogonidae (mainly genus *Culicoides*), with less than one and half thousand species, or the order Siphonaptera, the fleas, with slightly more than two thousand species, and even mosquitoes, Culicidae, with less than four thousand species. The family Tabanidae includes four subfamilies divided into tribes: Chrysopsinae (Bouvieromyiini, Chrysopsini, and Rhinomyzini), Pangoniinae (Mycteromyiini, Pangoniini, Philolichini, and Scionini), Sepsidinae, and Tabaninae (Diachlorini, Haematopini, and Tabanini). The most diverse genus is *Tabanus* (Fig. 7A) (with 1340 described species), followed by *Haematopota* (Fig. 7B) (556 species), *Chrysops* (287 species), *Hybomitra* (243 species), *Dasybasis* (176 species), *Cydistomyia* (146 species), *Philoliche* (124 species), *Scaptia* (119 species), *Esenbeckia* (111 species), *Stenotabanus* (100 species), *Fidena* (99 species), *Dichelacera* (80 species), *Atylotus* (76 species), *Catachlorops* (66 species), and *Mesomyia* (58 species) (Pape and Thompson, 2020). Most of the economically important tabanids are in the subfamily Chrysopsinae, particularly the genus *Chrysops*, and the subfamily Tabaninae (Mullens, 2002). Besides Tabanidae, also females of some genera of the families Athericidae and Rhagionidae (belonging to the infraorder Tabanomorpha) take blood from their hosts but are not involved in the pathogen transmission.

Fig. 7 Colorized SEM photo of *Tabanus* sp. (A) and *Haematopota* sp. (B) heads. Photo: Jana Bulantova.

At present, the tabanid identification is predominantly based on morphological characters; however, the generalized morphology, the rarity of male specimens, the use of variable characters like body and wing color, and in some cases the lack of reliable taxonomic characters in this family make species identification very difficult. In light of the identification problems using traditional taxonomic tools, molecular-based approaches have started to be used to solve some of these problems (Votýpka et al., 2019). The DNA barcoding region of mitochondrial cytochrome oxidase subunit I (COI) has been shown to effectively discriminate tabanid species (e.g., Cywinska et al., 2010; Banerjee et al., 2015; Changbunjong et al., 2018; Votýpka et al., 2019; see also the BOLD database: <http://www.boldsystems.org>).

Morphology

These robust and sturdy flies are strong fliers and exhibit body size ranging from 5 to 33 mm: horse flies (*Tabanus* and *Hybomitra*, just to cite key examples) are relatively large (10–33 mm) whereas deer flies (*Chrysops*) and clegs (*Haematopota*) are significantly smaller (5–13 mm). Adults are stout-bodied flies with a striking appearance, variously colored from black through brown to greens and yellows, bold stripes, and large brilliant colored eyes (Fig. 8), all providing useful taxonomic characteristics. The large, semi-lunar head bears two prominent eyes, which, in the live insects, are often patterned with iridescent reds and greens that usually fade after death. The eyes are commonly spotted in *Chrysops* spp., have zig-zag bands in *Haematopota* spp., and horizontal stripes and no patterning in *Tabanus* spp. The males are easily differentiated from female flies because eyes show striking differences in the arrangement of eyes. Females are dichoptic where eyes are separated by frons while males are holoptic where eyes are contiguous. The larger eyes of males reflect a mating strategy dominated by visual cues. The larger dorsal ommatidia may be more sensitive to UV

Fig. 8 Tabanids have large brilliant colored eyes: horizontal stripes are typical for *Tabanus* and *Hybomitra* (A); zig-zag bands for *Haematopota* (B), and *Chrysops* has spotted eyes (C). Photo: Andrei D. Mihalca (A); Jana Bulantová (B and C).

light, allowing the male to detect a fast-moving female against the sky, and the smaller ventral ommatidia may be used to resolve visual details.

Feeding

Similar to nematoceran hematophagous flies (e.g., sandflies (Phlebotominae), blackflies (Simuliidae), biting midges (the genus *Culicoides*), and mosquitoes (Culicidae)), in the family Tabanidae adult males feed on plant extracts and nectars, while females exhibit both hematophagous as well as nectarophagous feeding habit. Both sexes drink water from pools, lakes, ponds and water reservoirs in flight. In general, blood meal is necessary to carry out gonotrophic cycles in hematophagous insect females. Almost all tabanids are hematophagous, except for those who exhibit autogeny, a process where usually a single gonotrophic cycle can be completed without any blood meal (e.g., *Tabanus nigrovittatus*, *Apatolestes actives*, *Chrysops atlanticus*, *Chrysops fuliginosus*, *Chrysops hirsuticallus* or *Brennania hera*). However, many other species (e.g., *Hybomitra kaurii*, *Heptatoma pellucens*, *Haematopota pluvialis*, and *Haematopota crassicornis*) seem to be (facultatively) autogenous in the first gonotrophic cycle, probably reflecting genetic variability and the carry-over of available nutrients from the larval stage (Krčmar and Marić, 2010).

Tabanids locate their vertebrate hosts mainly by color and movement. The dark color is more attractive and dark-colored hosts, or even dark areas on black and white animals (e.g., Holstein cow), are often favored for an attack. A very interesting aspect of defense mechanism against the bite of various hematophagous arthropods, mainly tabanids, is the pattern of contrasting black and white stripes of zebras. This has been demonstrated on several occasions through experimental studies and field observations and reviewed recently by Caro et al. (2019). Moreover, this seems to be the primary role of the zebra stripes, and other possible functions such as camouflage, confusion of predators, signaling to conspecifics, and thermoregulation have not been validated. The visual repellent effect seems to work also against other biting dipterans such as tsetse flies and stable flies belonging to the genus *Stomoxys*. However, the mechanism of how these stripes prevent flies to bite zebras is not yet understood (Caro et al., 2019). Many tabanids are selective in attacking specific body regions of their hosts, regardless of color. For example, *Chrysops* spp. and *Haematopota* spp. usually feed high on the body (e.g., head and shoulders), legs are more favored by *Tabanus* spp. and *Hybomitra* spp.

Ecology

Tabanids mostly occur in warm areas with suitable moist locations for breeding, but also occupy a wide range of habitats from deserts to alpine meadows and they are found from sea level to at least 3300 m. They are largely seen in warm days with low wind speed; adult females bite during the daytime and are especially active in the sunshine. Their preferred habitat seemed to be bushy areas or grassland near aquatic bodies or wetlands. Females are often found nearby their hosts, mostly seen in and around cattle in rural areas. Adults generally take rest on tree trunks after feeding. They are almost all diurnal in the habit (but a very few species feed at dusk and during the night, particularly in the tropics) and found to breed near aquatic bodies. Although adult tabanids are strong fliers capable of considerable movement away from the breeding site and may actively travel several kilometers, they do not normally become widely dispersed.

In both temperate and tropical countries, the occurrence of adults is seasonal. In the tropics, populations often reach a peak towards the beginning of the rainy seasons; in temperate areas, the maximum is in the early summer.

Life cycle

The eggs (1–3 mm long) of tabanids are laid usually in a single compact mass (different species produce between 100 and 1000 eggs in a cluster; a few species lay several smaller batches of eggs), usually on the lower surface of leaves overhanging the water, on small branches, grasses, rocks, and stones or vegetation near water (ponds or streams), or simply on wet soil. Surfaces chosen for egg-laying are often species-specific (in general, *Haematopota* prefers relatively dry soil, *Tabanus* wet soil close to water bodies, and *Chrysops* wet mud often in semi-submerged situations). Eggs are white when laid but darken to grey, brown, or black within several hours and hatch in 1 or 2 weeks; however, in high temperature (about 30 °C) egg hatch can occur within 2 or 3 days.

Tabanid larvae are found in a wide variety of aquatic and semiaquatic habitats. Larvae pass through (four) six to nine (eleven) stadia and the time spent in the larval stage can last from a few months to one or two (for some species even three; e.g., *Tabanus atratus*, *Tabanus calens*) years. In temperate zones, most species overwinter in the larval stage and have only one generation per year (univoltine): adults usually die off at the end of the summer, with a new adult population emerging the subsequent spring. In the tropics, tabanids may produce two or more generations per year (multivoltine). Mature larvae of Tabanidae are usually 12–50 mm long, color varies from white to green, rather maggot-shaped, cylindrical, elongate, and fusiform, with a pigmented, retractile, sclerotized head capsule, and have distinct, raised, tire-like rings encircling three thoracic and eight abdominal segments with six protuberances called pseudopods (that can often be found on segments 4–10). Larvae of most species of the family Tabanidae are carnivorous (and cannibalistic) except first and second instars which are non-feeding, while the majority of *Chrysops* larvae are saprophagous, feed on detritus and decaying vegetable and animal matter. Even though most of the larvae are aquatic, semiaquatic, or edaphic and like muddy sites, they breathe in air through the very short siphon positioned on the last body segment. Mature larvae before pupation migrate to places of lower humidity.

Pupation usually occurs in drier soil near the larval habitat, with the head end oriented upward. The pupa obtecta (i.e., the pupae are capable of limited movement), which is brown and glossy, usually 10–33 mm long, is unlikely to be submerged. The pupal period varies from approximately 1 to 3 weeks and is temperature-dependent (Chvála, 1980; Chvála and Ježek, 1997).

The adult fly emerges from the pupal case via a slit located along the thorax of the case (circumscriptional names Orthorrhapha vs. Cyclorrhapha). The sex ratio is approximately 1:1, and the emergence of males precedes that of females by one to a few days.

Tabanid females usually mate before they seek a vertebrate host. Mating occurs in flight after virgin females enter male swarms. In canopy-inhabiting forest species, swarming happens above the canopy, but also along forest roads, ecotones, or above natural features (serving as markers), normally in the early morning or late afternoon. The male aggregations at the tops of hills (“hilltopping”) are common for some species. A few species are autogenous, but most require a blood meal for egg maturation. Following a blood meal, egg development takes typically 3–4 days, depending on temperature; however, time to oviposition may be several days longer.

Due to their very complex and long-time life cycle, predaceous and cannibalistic habits, and requirement of specific conditions including hibernation (for temperate species) and mating in flight (the key barrier to colonization), no tabanid species has been successfully colonized. However, several methods were described for rearing immature horse fly stages (e.g., larvae collected in mud, damp soil, humus, muddy waters, on the edges of pools and ponds, or adhere to floating vegetations) by using various substrates (including soil, bryophytes, or sand) for maintenance of horse fly species including those with a long development (see Ferreira and Rafael, 2006).

Epidemiology

In general, most tabanid species are highly seasonal, with great variations (even intraspecific) between geographical regions. There are several studies available on the seasonality of tabanids in various regions of the world, both in the northern and southern hemisphere and various ecoregions (Noireau et al., 1991; Baldacchino et al., 2014b; Krüger and Krolow, 2015; Lucas et al., 2020). In temperate regions, the peak activity is during the summer, and often short. In tropical regions, tabanids are more active during the rainy or humid seasons, but with great variation depending on the species (Baldacchino et al., 2014a). In certain areas, a seasonal succession of species has been described (De Liberato et al., 2019).

Female tabanids are diurnal insects and their activity is influenced by the photoperiod. Certain species have one peak per day (unimodal) (i.e. at noon), others have two (bimodal) (i.e. morning and afternoon). The activity during the day is influenced by climatic factors such as temperature and wind speed. They generally prefer the warmer hours of the day in temperate areas, and the cool mornings and evenings in tropical areas (Baldacchino et al., 2014a).

Prevention and control

As tabanids are a nuisance, as well as vectors of causative agents of several important diseases for animals and humans, there is an increased interest in their population control. However, the efforts have never reached the intensity of those invested in the control of other arthropod vectors such as mosquitoes. Moreover, control measures should be usually based on surveillance data, which is again far less plentiful than in the case of most other vectors. As summarized by Baldacchino et al. (2014a), the effective tabanids population reduction is challenging due to several factors related mostly to the biological features of these insects: short on-host hematophagous feeding period, use of multiple hosts for the blood meal (including wildlife), and a great variety of the biotopes use for oviposition and larval development.

Several control measures are possible, some of them only at the theoretical level, as they have rarely or never been implemented into current practices. As a curiosity, we can mention a field experiment suggested that the striped coats of zebras can prevent biting and cows painted with zebra-like striping can avoid biting fly attacks including tabanids (Kojima et al., 2019). There are very few practical measures that are effective in reducing tabanid populations. All of them have been detailed in the review by Baldacchino et al. (2014a) and will be summarized below. One of the ideal options is the use of biological control. Despite the existence of numerous pathogens, parasitoids, and predators of tabanids, there were only a few experimental approaches for this. Management of grazing seems to be an efficient method to reduce the intensity of tabanids attacks. Several studies have shown that various tabanid species are more active along the forest edges, so such areas should be avoided when grazing livestock or horses. Another suggested approach could be moving the livestock to higher altitude pastures during the peak tabanid season. Due to their obstacle avoiding flight behavior, tabanids will less likely attach hosts in shelters (even basic ones), or behind solid physical barriers.

Several chemical-based approaches are available for livestock, including pyrethroids such as permethrin, cypermethrin, deltamethrin, fenvalerate applied as pour-on, sprays, or ear tags. The reported success varies as efficacy and duration with the study, concentration, and route of application. The use of repellents is a desirable method, which should prevent tabanids from landing and biting the host. The most efficient seems to be the DEET, applied by spraying at a concentration of 75%, which protects horses for 3–4 h but induces dermatological side effects. Oxamate 20% was also efficient for 12 h when used on cattle. Plant-derived essential oils have also been used with variable efficacy (Benelli and Pavela, 2018). However, all these repellents have the disadvantage that they have a short-lasting effect (Baldacchino et al., 2014a); thus, nanoencapsulated formulations boosting their efficacy over time can be considered in further research. Placing various types of traps around livestock flocks is a control

method that is also being used. These traps (consisting of colored screens (blue, black, or red) coated with various adhesives) can be un-baited or they can use various attractants as baits such as CO₂, 1-octen-3-ol, ammonia, and phenols, or aged mammalian urine (Baldacchino et al., 2014a); however, they are no real solution for combating tabanids.

The control of tabanids which are vectors for human disease (i.e. *Chrysops*) is not currently being considered in public health programs in Africa. Some of the methods presented above for livestock have been also occasionally documented for the prevention of human bites in Africa and they included also the destruction of tabanid habitats (see Kelly-Hope et al., 2017).

Conclusions

Despite their great diversity and medical and veterinary importance, tabanids are a neglected group of hematophagous arthropods. Their study is relatively difficult also because there are no laboratory colonies available. Their control is also difficult for several reasons, and they continue to be a permanent nuisance, in many regions only seasonally.

Introduction

The non-biting flies as the house fly (*Musca domestica*) and the face fly or autumn house fly (*M. autumnalis*) together with biting flies like the stable fly (*Stomoxys calcitrans*) and the horn/buffalo flies (*Haematobia irritans/exigua*) are responsible for the considerable annoyance of host animals. Wheals, crusts, and cutaneous papules and nodules have mainly been associated with the biting flies *Stomoxys* and *Haematobia* and several tabanid species. The four closely related and morphologically similar muscoid genera, *Stomoxys*, *Haematobia*, *Haematobosca*, and *Haematostoma* are widely distributed in tropical and subtropical areas with some species spread also in a temperate zone. The stable fly (*S. calcitrans*) and the horn/buffalo flies (*H. irritans/exigua*—see “[Taxonomy and diversity](#)” section) are major livestock pests that cause substantial economic losses in the cattle/buffalo industry and are vectors of many parasites and pathogens.

Horn flies are among the most economically important blood-sucking ectoparasites that affect the health and well-being of pasture livestock, particularly cattle and buffaloes. The repetitive bites of horn flies, both males and females, can lead to reduced weight gain, decreased milk production, and skin lesions. The flies cause billions of dollars of damage and loss to the cattle industry each year; however, the economic losses vary significantly among regions because environmental conditions significantly affect the growth of horn fly populations. Horn flies are vectors of several filarial nematodes such as *Stephanofilaria stilesi* in North America and *Stephanofilaria assamensis* and *Parabronema skrjabini* in Asia. They can also serve as mechanical vectors for several important pathogens of livestock (see “[Mechanical transmission](#)” section).

The adult fly (Fig. 1) is 3–5 mm long with piercing/sucking mouthparts that are painful to cattle. They are ferocious and painful biters and both sexes take blood meals multiple times a day, even more than 20 ×. Flies are in continual contact with the hosts, resting on them between feedings, and can be seen mainly on the withers, shoulders, back, and side and will move to the underbelly during the hottest parts of the day. More than 400 flies per animal will affect the health and productivity and treatment is recommended when fly counts exceed 200. Larvae breed in undisturbed dung pats, and adult populations build up during the warmer months of the year.

Medical and veterinary importance

Horn flies are particularly important as veterinary parasites, but occasionally they can also feed on humans. Their veterinary and medical importance resides in their direct effect (painful bite, blood loss, allergic reaction, decreased productions with economical loss) and their vectorial role (both biological and mechanical). All these are summarized below.

Direct effect of horn flies on their hosts

Horn flies occur mostly on the adult cow or buffalo and usually only incidentally on the calves (Moon, 2019). They usually feed along the dorsal part of the body but also the sides and ventral abdominal region. Due to their blood-feeding behaviour which involves multiple and repeated withdrawals and re-insertions of the mouth parts, the cutaneous irritation and inflammatory response

Fig. 1 *Haematobia irritans*. Photo Andrei Daniel Mihalca.

are considerable. The bites of *H. exigua* cause cutaneous hypersensitivity in cattle (Kerlin and Allingham, 1992). As for other biting dipterans, the nuisance is significant and impairs normal feeding (Wall and Shearer, 1997). Infested cattle react by licking their backs, twitching their flanks, switching their tails, and kicking at their bellies with their hind legs (Moon, 2019).

In addition to the excessive number of painful bites that occur daily, the lesions can lead to secondary infections and cosmetic defects in tanned or dyed leather (Moon, 2019). One of the significant impacts of horn flies is the economic loss on the cattle industry. The direct economic losses are though linked to decreased milk production, associated with decreased weaning weights of calves but also to decreased weight gains (Foil and Hogsette, 1994). Heavy attacks by horn flies were shown to cause a 25–50% decrease in milk production (Wall and Shearer, 1997). Studies (summarized by Foil and Hogsette, 1994) showed that in North America, a level of 200 horn flies per animal is considered to financially justify the implementation of control measures. Not treating highly infested cows can lead to a one-tenth decrease in the average daily growth rate of nursing calves. The growth rate of yearling stocker cattle and lactation rates of dairy cows may decrease by about 15%. Metabolic and behaviour responses indicate that horn flies increase the amount of energy spent by cattle when defending themselves, leaving less energy available for growth.

Vectorial role

Horn flies are biological vectors (and intermediate hosts) for various filarial nematodes of herbivores (Anderson, 2000) but also mechanical vectors for viruses, bacteria, and protozoans.

Biological transmission

Haematobia irritans and *H. titillans* are biological vectors for the filarioid nematode *Stephanofilaria stilesi* (Anderson, 2000). The role of horn flies as vectors for *S. stilesi* was suggested by Dikmans (1934), but only later (Ivashkin et al., 1963; Hibler, 1966) demonstrated their role. *Stephanofilaria stilesi* causes a circumscribed granular or crusty dermatitis mainly along with the medio-ventral line of the body of cattle (udder, belly, scrotum, and prepuce) (Foil and Hogsette, 1994; Anderson, 2000; Russell et al., 2013). Males and females of *H. irritans* feed on the cutaneous lesions and engorge blood contained the L1 of the nematodes. In the abdominal hemocoel, they undergo two molts and become infective L3 in ca. 18–21 days at room temperature (Hibler, 1966). As horn flies prefer to feed on adult cattle, stephanofilariasis is more common in these, compared to calves (Anderson, 2000). Another member of the genus *Stephanofilaria*, namely *S. assamensis* has been shown to be transmitted by its intermediate host, *H. titillans* (Anderson, 2000).

Haematobia irritans is a vector for *Habronema microstoma* (Russell et al., 2013), a gastric spirurid of horses, while *H. titillans* is a biological vector of *P. skrjabini* (Ivashkin, 1959; Anderson, 2000), a spirurid nematode inhabiting the abomasum of various species of ruminants in Africa, Asia, and some Mediterranean countries (Hasheminasab et al., 2016).

Another horn fly species, *Haematobosca stimulans*, is a biological vector for *Setaria cervi* (Osipov, 1966), a filarial parasite of the abdominal cavity and central nervous system of various cervids in Eurasia (Anderson, 2000). The infective stage in the flies develops in ca. 23 days (Anderson, 2000).

Haematobosca atripalpis is a biological vector for *Parafilaria multipapillosa* (Gnedina and Osipov, 1960), a parasite of the subcutaneous and intermuscular connective tissue of equids in the Old World and South America where it causes the disease known as “bloody sweat” or “summer bleeding” (Anderson, 2000). The larvae reach the L3 infective stage in 10–15 days at 20–36 °C (Anderson, 2000).

Mechanical transmission

Due to their frequent hematophagous feeding behaviour, horn flies, together with tabanids, are considered among the most important mechanical vectors, mainly about the diversity of transmitted pathogens (Baldacchino et al., 2018). However, from an epidemiological point of view, due to their rather sedentary behaviour (they tend to rest on the same animals between blood meals), horn flies are not as efficient as tabanids and other biting muscids in spreading diseases via a mechanical transmission (Russell et al., 2013).

Horn flies are important mechanical vectors for the summer mastitis caused by *Staphylococcus aureus* associated with other bacteria (Owens et al., 1998; Baldacchino et al., 2018). Summer mastitis is more severe during the increased activity of horn flies, and the control of flies decreases the incidence of teat lesions (Ryman et al., 2013).

Horn flies have been implicated or suggested as mechanical vectors for other bacterial pathogens such as *Salmonella enterica* (Olafson et al., 2014), *Staphylococcus saprophyticus*, *Morganella morganii*, and *Serratia marcescens* (Palavesam et al., 2012). Apart from non-transferable symbiotic *Midichloria*- and *Wolbachia*-like bacteria (Hornok et al., 2008; Zhang et al., 2009; Torres et al., 2012), various other microorganisms have been detected in *H. irritans*, but the mechanical transmission has not been demonstrated. Examples include the Nora virus and *Mycobacterium bovis* in Mexico (Torres et al., 2012) or *Mycoplasma wenyonii* in Hungary (Hornok et al., 2008, 2011).

Under experimental conditions, *H. irritans* was suggested as a mechanical vector for the bovine leukaemia virus (Buxton et al., 1985; Panei et al., 2019) and bovine viral diarrhoea virus (Chamorro et al., 2011).

The mechanical transmission by *Haematobosca squalida* is known also for the kinetoplastid *Trypanosoma brucei brucei*, the agent of Nagana in Africa (Mihok et al., 1995; Baldacchino et al., 2018). A high incidence of the bovine besnoitiosis caused by the apicomplexan parasite *Besnoitia besnoiti* was associated with the peak activity of biting flies, including *H. irritans*, but its vector role has not been demonstrated (Gollnick et al., 2015).

Haematobia flies from South America have been shown to be phoretic carriers of the eggs of the human bot fly, *Dermatobia hominis* (Pont, 1973; Leite et al., 1998).

Biology and ecology

Taxonomy and diversity

The following four biting muscid genera: *Stomoxys* (e.g., the stable fly *S. calcitrans*), *Haematobia* (e.g., the horn fly *H. irritans* and the buffalo fly *H. exigua*), *Haematobosca* (e.g., the large horn fly *H. stimulans*, the moose fly *H. alcis*, and *H. sanguinolenta*), and *Haematostoma* (*H. austeni*) are true flies (order Diptera) belonging to the family Muscidae, subfamily Muscinae, and tribus Stomoxyini (sometimes are placed in the separate subfamily Stomoxyinae or even family Stomoxyidae). (There is one more genus, *Stygeromyia*, with two species distributed in Sub-Saharan Africa and Oriental region; however, the existence and the systematic status of this genus are disputed.) Stomoxyini biting flies, comprising almost 50 species, are obligate blood-sucking ectoparasites of livestock and other warm-blooded animals, and some species are considered important pests of domestic animals with a significant economic impact in many parts of the world. The genus *Stomoxys* contains 20 described and currently accepted species, the genus *Haematobia* accommodates 9 species, the genus *Haematobosca* is comprised of 17 species, and the last genus *Haematostoma* is represented by only one species, *H. austeni* (Pape and Thompson, 2020).

In addition to the cosmopolitan species *S. calcitrans*, several other *Stomoxys* fly species, including *S. niger*, *S. sitiens*, and *S. indicus*, also readily attack domestic animals (Wall and Shearer, 1997).

The horn fly species *H. irritans* has been originally described by Linnaeus as *Conops irritans* Linnaeus, 1758; however, Lepeletier and Serville established in 1828 the genus *Haematobia* where, later, this species was accommodated. Unfortunately, the generic name *Siphona* Meigen (1803) and *Lyperosia* Rondani (1856) were also introduced (as *Siphona irritans*, *Lyperosia irritans*, or *Siphona* (*Lyperosia*) *irritans*) into literature and have been commonly used in 19th and 20th centuries.

The well-known and cosmopolitan horn fly *H. irritans* is in some geographical areas substitute by the buffalo fly *H. exigua*. The horn fly is a significant pest of cattle throughout much of the world; originally it is distributed in the Holarctic region—in Europe, North Africa, Anatolia, and central Asia, the distribution in East Asia is questionable. The species was accidentally introduced by humans and livestock to North America in the middle 1880s. It was first reported in Canada in the early 1890s; it colonized most of the continent and had reached Venezuela by the 1930s. Horn fly arrived in Brazil in the mid-1980s and has spread through much of the cattle-producing areas of North and South America, including Hawaii. The buffalo fly is an important pest in northern Australia and Southeast Asia. The species is native to southern Asia, the Orient, Indonesia, and several Pacific islands and it spread through commerce to New Guinea and Australia before 1840. Both species have occurred together through the boundary of the Palearctic and Oriental regions. The horn and buffalo flies are closely related to each other (sometimes referred to as *H. irritans sensu lato*) and the morphological differences are very minor (e.g., presence/absence of 4–6 long hairs with curled tips on the second segments of the male's hind tarsus). These two flies have often been regarded as different species or as subspecies (*H. irritans irritans* and *H. irritans exigua*). The current chemotaxonomic research (Urech et al., 2005) and studies based on molecular divergences between these two taxa indicate an intermediate status between intraspecies and interspecies genetic variability (Iwasa and Ishiguro, 2010; Low et al., 2014; Changbunjong et al., 2016; Onder et al., 2018); however, the current universally accepted agreement is to keep them as two separate species.

In addition to *H. irritans* s.l., several other species affect domestic animals, among them *Haematobia titillans* (also referred to as *Lyperosia titillans*; for the reason see above) is the most important. The species is found in the Palaearctic region, namely in southern Europe, Turkey, the Central Asian Republic, and throughout the southern part of Russia reach to India and China; in many areas is associated with *H. irritans*. Like in other Stomoxyini flies, larvae are coprophagous and develop in many kinds of ungulate dung; however, *H. titillans* is quite often associated with camels where is the most numerous biting flies. The species is, together with *H. irritans*, an intermediate host of the nematode *P. skrjabini*, the causative agent of camel parabronchitis, and the nematode *Stephanofilaria assamensis* that causes common chronic ulcerated growth ("humpsore") in the Central Asian Republics and East Asia.

The genus *Haematobosca* is relatively species-rich, with 17 currently accepted and formally described species. The best-known species *Haematobosca stimulans* (also referred to as *Haematobia stimulans*) is in some areas so-called the large horn fly or large meadow bite fly. The fly with a length from 5 up to 7 mm is native to Europe and Asia and was introduced with cattle in North America. Its activity is mainly in late summer and autumn (e.g., in Europe flight from May to October) when heavy infestations with about one hundred flies per animal can occur. The species is associated mainly with cattle and other bovids; however, flies occasionally occur also on other big animals, like on horses. Adults are found on or around cattle and on/in farm buildings. Eggs are laid in almost fresh cow-dung and there are up to four (rarely five) generations per year. Adults sit on cattle with the head upwards, which distinguishes them from *H. irritans*. While the horn flies *H. irritans* practically live on the host, *H. stimulans* leave the host and spend the night at resting places in the vegetation.

In North America, another, morphologically very similar species of the genus *Haematobosca* is associated with cervids, specifically with the moose/elk (*Alces alces*). The association of the moose fly, *H. alcis*, with its host is intimate and flies could be found in greatest numbers on those parts with the least or shortest hair (e.g., on the calcaneum, around the anus, and on the hindquarters) and even more than 500 flies per animal were recorded (Burger and Anderson, 1974). The development from egg to adult in moose excrement requires approximately 3 weeks and flies could have completed as many as five generations per year (Egan and Moon, 2013). In the temperate zone, similar to other *Haematobia* spp. and *Haematobosca* spp., only the pupal stages overwinter.

The third notable species of this genus is *H. sanguinolenta*, commonly found in livestock farms, but also zoos and national parks in tropical Asia (Changbunjong et al., 2012).

The monotypic genus *Haematostoma*, represented with the only one species, *H. austeni*, is known from Oriental regions. The species has been reported as a jungle fly attacking big mammals, but it has rarely been collected despite its wide distribution in Southeast Asia including Borneo, Malaysia, Laos, Myanmar/Burma, and Thailand.

Morphology

The adult horn/buffalo flies (*H. irritans* s.l.) live in close association with cattle or buffalo. The fly is about 3–5 mm long, thus significantly smaller than the stable fly (*S. calcitrans*) with body length 4–7 mm or the large horn fly (*H. stimulans*) 5–7 mm long. A noticeable feature of the horn/buffalo flies is that they sit close together (forming a typical swarm) and with their heads pointing downwards on the hosts (Fig. 2). They do not walk over the surface of the bovid but fly to change position.

The colour of the body is grey, with four dark stripes on the top of the thorax. The wings are broad (Fig. 3) and spread in a delta-shaped manner (held at a 45–60° angle to their bodies) at rest (Figs. 1 and 2). The eyes are large and red, widely spaced in the females and close together in the males. The mouthparts are similar to the stable fly with a heavily sclerotized labium that forms the sheath of the proboscis. The food canal is formed by the labrum-epipharynx and the hypopharynx forms the salivary canal. The labium ends in a pair of labella that bear sharp teeth used for cutting the host's skin. Species of *Haematobia* and *Haematobosca* may be readily recognized by the possession of an elongate, sclerotized proboscis, with palps that are as long as the proboscis and which are grooved internally. The palps extend in front of the head and are distinctly dilated towards their tips. On the other hand, the palps of the stable fly (*Stomoxys*) are almost invisible. In the genus *Haematobosca*, arista (a bristle arising from the third antennal segment) carries hairs on the dorsal and ventral side, contrarily in *Stomoxys* and *Haematobia* the arista carries hairs only on the dorsal side.

Feeding

In contrast to nematoceran hematophagous flies (e.g., sand flies (Phlebotominae), blackflies (Simuliidae), biting midges (the genus *Culicoides*), and mosquitoes (Culicidae)) and horse flies (family Tabanidae), both males and females of all species of the tribus Stomoxyini (*Stomoxys*, *Haematobia*, *Haematobosca*, and *Haematostoma*) are hematophagous, similar to tsetse flies and hippoboscids flat-flies.

Although cattle and water buffalo are known to be the primary and preferred hosts for *H. irritans* and *H. exigua*, respectively, occasional feeding on other domestic animals including bison, camels, horses (Onder et al., 2018), and dogs (Kuramochi, 2000) have also been reported, sometimes in a very high density (e.g., over 500 horn flies per a horse were observed in Turkey, Onder et al., 2018). Biting on humans was also rarely observed (Marchiondo, 1987). In contrast, the stable fly is much less host-specific and its frequent attacks on people moving around typical hosts are well known.

The horn/buffalo flies stay on animals almost continuously and taking 20 or even more blood meals each day with their stiff needle-like mouthparts. They take frequent small blood meals, with each fly consuming on average 10 μ L of blood per day. Persistent blood-feeding irritates (so that's why the species name is "*irritans*") hosts and can cause significant production losses. Irritations from the bites annoy animals and occasionally, the wounds may become infected. In heavy infestations, the injection of salivary antigens stimulates the formation of circulation antibodies in highly variable concentrations. Like in other hematophagous arthropod species, the success of blood-feeding in *H. irritans* s.l. is highly dependent on its complex salivary mixture delivered at the bite site and the modulation of the host's haemostasis and immune system. It is well known that saliva from hematophagous arthropods facilitates the availability of blood as well as the transmission of etiological agents of various infectious diseases. It has been emphasized that *H. irritans* shows host specificity which relies on physiological adaptation to blood-feeding. These flies include two forms of a trypsin-like enzyme and an aminopeptidase in their midgut and Kuramochi (2000) demonstrated that aminopeptidase activity is lower in flies fed with blood from other animals than that in flies fed with cattle blood which indicates blood proteins from other hosts may not be able to digest by the horn flies. In addition to this, in the *H. irritans* saliva, a bioactive protein hematobin (HTB) has been recently identified with its ability to modulate macrophage inflammatory response (Breijo et al., 2018).

Life cycle

The horn/buffalo flies (*H. irritans* s.l.) occur worldwide, suck blood more than 20 times per day, and develop four to five generations per year. The life cycle and development of horn flies are primarily correlated with environmental temperatures and the presence of suitable hosts and manure (Lysyk, 1992). When the larvae are exposed to declining temperatures in autumn (in temperate

latitudes), pupal diapause occurs, and the adult flies emerge at the beginning of the following spring especially in temperate areas (Lysyk and Moon, 1994). Horn fly females usually only mate once, and this occurs on the host, and can oviposit on the second day after emergence. They lay eggs on fresh cattle manure only, specifically under edges of dung pat within minutes of defecation, usually up to 10 min of it hitting the ground. Horn fly maggots only develop in cattle manure and do best in the grass manure of pastured cattle; dung from other hosts (e.g., horses and sheep) remain unnoticed. Each female can lay up to 400 eggs (in batches of 20–30 eggs) so very large populations can build up over the summer. Eggs hatch within 1–2 days. The larvae are off white and have a tapered appearance on one end and rounded on the other end. After passing through three instar stages, the larvae develop to pupae (3–4 mm in length) in the manure at days 4–8, depending on environmental temperature (Lysyk, 1991; Lysyk and Moon, 1994). Pupating takes place within the dung pat or in the nearby soil and adults emerge 6–8 days later and should find a host quickly for their first blood meal. Adult horn flies spend most of their life on their host and feed multiple times a day. They leave their host only for laying eggs and/or moving to another host. The life cycle is completed in 10–18 days.

Epidemiology

Haematobia irritans is native to the Old World (Africa, Europe, and central Asia). It was introduced into North America from Europe in the middle of the 19th century and since then it has spread to most regions of the world where cattle are present. *Haematobia exigua* is native to Asia and some Pacific islands and has spread to Australia and New Guinea in the first half of the 19th century. Although the main hosts are large ruminants (cattle, bison, and water buffaloes) they can use aberrant hosts such as horses and other large mammals, and occasionally they can bite humans. However, larval development can take place only in the dung of their typical large ruminant hosts (Moon, 2019).

Several host-related intraspecific factors such as genetics and cattle breed seem to influence the infestation levels with *H. irritans* (Guglielmone et al., 2000; Calkins et al., 2019). It is unclear which factors are responsible for such differences but hair density and sebum quantities have been incriminated (Steelman et al., 1997). Horn fly resistant lines are known (McKay et al., 2019).

The seasonal variation in the activity of the horn flies is influenced by various factors such as the temperature emergence threshold (Scasta et al., 2017). In temperate areas, horn flies are present throughout the whole summer season (Fowler et al., 2015) and the overwintering is as diapausing pupae (Moon, 2019). In tropical regions, seasonality is influenced rather by the rainfall, with high peaks after the rain season (Ferraz da Costa et al., 2014). In subtropical regions of South America (e.g., Uruguay) the peak is in late summer and early autumn, and up to dozen generations per year is possible (Castro et al., 2008). The infestation levels are also dependent on the grazing system. A study from Brazil showed that *H. irritans* is more likely to occur on cattle from conventional pasture systems than from silvopastoral systems (de S Oliveira et al., 2017).

Prevention and control

Compared to other biting dipterans such as horse flies, stable flies, or mosquitoes, the control of horn flies has been considered easier, mainly to the behaviour of adults who spend most of their time (feeding or resting) on the body of their hosts. Hence, the application of insecticides on cattle is usually successful in reducing the populations (Foil and Hogsette, 1994). However, this success may be partially tempered by the development of insecticide resistance which has been reported to organochlorines, organophosphorus compounds (both banned or with very limited uses nowadays), and pyrethroids (Foil and Hogsette, 1994). Adulticides can be applied to animals through various routes such as sprays, pour-ons, wipe-ons, or various self-application devices (ear tags, dust back, or back rubbers) (Foil and Hogsette, 1994; Russell et al., 2013). Repellents are generally considered to have a limited effect on horn flies (Russell et al., 2013). In contrast, semiochemical tools to attract and trap horn flies could be considered (reviewed by Brugman et al., 2018).

Considering the biology of the reproduction of horn flies, the removal of the manure is also an effective way to limit the larval development and adult emergence. Various types of artisanal trapping systems have been tested, some of them with acceptable efficacy (Foil and Hogsette, 1994). Biological control measures such as habitat competition for larvae by dung beetles, predation by other insects (Staphylinidae and Histeridae beetles) and mites, entomopathogenic fungi (reviewed by Weeks et al., 2018), or bacteria (Baldacchino et al., 2018) have been evaluated but with various success rates (Foil and Hogsette, 1994).

The use of insecticides in a feed (benzamides, insect growth regulators, or avermectins) of cattle has been shown to be effective and limit the larval development due to elimination in the dung (Brugman et al., 2018). However, such methods can pose a significant threat to free-living arthropods and the opportunity to use this should be evaluated with care.

Several vaccine candidates (e.g., recombinant salivary gland protein, hematobin) were evaluated against *H. irritans* (Cupp et al., 2004; Breijo et al., 2017), but they have not yet been implemented as a control measure under field conditions.

In summary, control measures should be applied only when horn flies are abundant enough to justify it economically and integrated pest control measures (e.g., insecticide application and manure removal) are preferable to achieve maximum efficacy.

Glossary

Biological vector The pathogen infects the vector and undergoes reproduction or develops from one stage to another. Also referred to as a cyclical vector.

Dead-end host A host for a pathogen that is not part of the transmission cycle or amplification of the pathogen.

Ectoparasites Parasite living on the outside of their host.

Hematophagous Feeds upon blood.

Intermediate host A host in which development takes place but not sexual reproduction.

Mechanical vectors No development or reproduction of the pathogen takes place within the vector.

Synanthropic Domestic or associated with humans and their habitations.

Introduction

Stable flies, *Stomoxys calcitrans* L., are hematophagous synanthropic flies. Originating in Africa or southern Asia and accompanied the introductions of European livestock to the remainder of the temperate and tropical world. Although the time of their arrival to North America is not documented, their presence in Philadelphia during the signing of the Declaration of Independence, 4 July 1776 was noted by Thomas Jefferson:

The weather was oppressively warm, and the room occupied by the deputies was hard by a stable, whence the hungry flies swarmed thick and fierce, alighting on their legs and biting hard through their thin silk stockings. Treason was preferable to discomfort.

(Fuller, 1913)

Most likely, stable flies arrived in the Americas along with the 1200 men, pigs, horses, and cattle on Columbus's second voyage in 1493. It is unlikely they would have been absent from this entourage. Stable flies are persistent and painful biters making them serious pests of livestock, wildlife, and humans throughout their range. It is estimated that they reduce the productivity of United States cattle industries by over \$2 billion per year (Taylor et al., 2012b). Using 2018 cattle inventories and commodity prices, their impact on cattle productivity is estimated to be \$2.66 billion.

In addition to stable fly, other common names for *S. calcitrans* include dog fly, biting house fly, and power mower fly. The common name stable fly, is usually used in a narrow sense, referring only to *Stomoxys calcitrans*. However, occasionally it is used more broadly, referring to the other species in the genus as well.

Medical and veterinary importance

With their painful bites and blood feeding activities, stable flies reduce the productivity and comfort of livestock and companion animals, interfere with human outdoor and recreational activities, and transmit pathogens causing human and livestock diseases. As for most ectoparasites, the damage they inflict can be considered either direct, that caused directly by the parasite, or indirect, that caused by pathogens transmitted by the parasite.

Direct damage

Stable flies' painful bites disrupt feeding, reproductive and resting behaviors of livestock and induce physiological stress. Most of the economic impact of stable flies can be attributed to direct damage, the behavioral and physiological responses of livestock in response to the flies feeding activity. Stable fly bites are more painful than other biting insects (Elzinga and Broce, 1986) causing discomfort and strong defensive behaviors in the hosts. In severe infestations, host mortality may be observed (Bishopp, 1913; Cook et al., 1999; Huchzermeyer et al., 2001; Elkan et al., 2009). Both male and female stable flies require blood meals for sustenance and reproduction. Adults blood feed daily, $\approx 11 \mu\text{L}$ of blood per meal (Salem et al., 2012) and females require 3–4 blood meals to develop each batch of ≈ 150 eggs (Harris et al., 1974; Jones et al., 1999). Adults are closely associated with their hosts only while blood feeding, $\approx 2\text{--}4$ min per day (Harris et al., 1974). Each fly in an instantaneous count on a host can represent up to 180 biting flies per day or 2 ml of blood loss per day. Infestations at the economic threshold level, ≈ 15 flies per animal (Berry et al., 1983; Campbell and Berry, 1989), can result in the loss of ≈ 30 mL of blood while an infestation of 1000 or more flies (Solórzano et al., 2015) can result in the loss of >2 L of blood per day.

Cattle react to stable fly attack with behavioral and physiological responses. Fly repelling behavioral responses include tail flicking, leg stamping, head throwing, and skin twitching (Mullens et al., 2006) and fly avoidance behaviors include moving into shaded areas or enclosures, standing in water, and "bunching" (El Ashmawy et al., 2019). These behaviors consume metabolic energy and interfere with grazing. In response to stable flies, cattle may shorten grazing periods, reduce overall daily grazing time and intake (Todd, 1964). Cattle infested with stable flies tend to consume herbage faster, but for shorter periods of time, than uninfested animals (Dougherty et al., 1994). Experimental results relative to physiological responses are ambiguous. Schwinghamer et al. (1986) observed increased heart rate, respiration rate, and rectal temperature among other physiological parameters when steers were exposed to stable flies, whereas Estienne et al. (1991) observed no changes in the same parameters. Previous exposure to stable flies moderates fly induced responses in cattle (Mullens et al., 2006; Schole et al., 2011).

During the last 30 years, stable flies developing in crop residues in fields have become an increasingly serious issue in diverse regions of the world, vegetable crop residues in Western Australia (Cook et al., 2018), sugarcane residues in Brazil and Mauritius (Dominghetti et al., 2015), and pineapple residues in Costa Rica (Solórzano et al., 2015). Prior to the use of combines, when grains were threshed in the field, similar observations were made in the United States where large outbreaks of stable flies were attributed to flies developing in straw piles (Bishopp, 1913). Outbreaks resulting from flies developing in crop residues are producing infestation levels in excess of 1500–2000 stable flies per animal (Solórzano et al., 2015). Infestations of this magnitude make livestock production impossible with negative weight gains, dry dairy cows, and mortality.

Indirect damage

Relative to other blood feeding flies, stable flies are poor vectors. Other than for the horse stomach worm (*Habronema microstoma*) stable flies act as mechanical vectors; no development or reproduction of the pathogens/parasites take place in the fly. Rather, the pathogen/parasite can be transferred on contaminated mouth parts or by regurgitation of gut contents while feeding on an uninfected host. In most cases, pathogen transmission by stable flies involves interrupted feeding and resumption on a different host within a short timeframe. Since stable fly infestations can be heavy and interrupted feeding very common (Schofield and Torr, 2002), although inefficient vectors, they can still play significant roles in the transmission of pathogens and parasites. Although they have been incriminated as vectors of several pathogens/parasites, the four criteria needed to demonstrate the vectorial role an arthropod (Barnett, 1960; Table 1) have been documented for very few. Most of the pathogens/parasites that stable flies have been implicated for transmitting are not currently present in North America. Unfortunately, several are invasive and rapidly expanding their ranges. Even though they are not currently a threat in North America, we need to remain vigilant and recognize that, should they invade, we have competent vectors capable of maintaining pathogens and resulting disease.

Table 1 Barnett's criteria for incriminating a vector.

1	Demonstration of feeding on or other effective contact with the host under natural conditions
2	A biological association in time and/or space of the arthropod and host
3	Repeated demonstrations that the arthropod, under natural conditions, harbors the pathogen
4	Transmission of the pathogen under controlled conditions

Barnett HC (1960) The incrimination of arthropods as vectors of disease. *Proceeding of 11th International Congress of Entomology*, vol. 2, pp. 341–345.

Viruses

Equine infectious anemia (EIA)

Equine infectious anemia is an infectious, viral disease of horses and other equids with worldwide distribution. The virus is an RNA virus in the family Retroviridae, genus *Lentivirus*. The disease, also known as Swamp Fever, is most active during seasons and at locations where biting flies are abundant (Scott, 1922). Deer flies (*Chrysops* spp.; Foil et al., 1983), horse flies (*Tabanus* spp.; Stein et al., 1942; *Hydrometra* spp.) and stable flies (*S. calcitrans*; Stein et al., 1942; Foil et al., 1983) can transmit the disease mechanically. The relative importance of these flies as vectors depends upon season and geographical region.

Lumpy skin disease (LSD)

Lumpy skin disease is caused by a virus in the family Poxviridae, genus *Capripoxvirus* which affects cattle and water buffalo in Africa, the Middle East, and recently, expanding into southeastern Europe (EFSA, 2019). Lumpy skin disease causes considerable economic losses due to emaciation, hide damage, infertility, mastitis, loss of production, and mortality (Davies, 1991; Al-Salihi, 2014). Outbreaks of LSD in Israel are associated with high infestation levels for stable flies (Kahana-Sutin et al., 2017). Stable flies can transmit LSD virus between sheep (Kitching and Mellor, 1986) and cattle (Sohier et al., 2019; Issimov et al., 2020). Stable flies and horse flies appear to be the primary vectors of LSDV.

Bovine leukosis

Enzootic bovine leukosis is a contagious retroviral disease of cattle caused by the Bovine Leukemia Virus (BLV). BLV infection degrades lymphocyte function in cattle, diminishing immune response, milk production and longevity. Approximately 40% of dairy cattle in the United States are infected with BLV. Annual losses to dairy producers and consumers exceed \$500 million per year (Bartlett et al., 2014). Biting fly control has a significant effect on the incidence of BLV in dairy herds (Kobayashi et al., 2010; Erskine et al., 2012). Although experimental transmission of BLV by tabanid flies has been demonstrated (Ohshima et al., 1981; Hasselschwert et al., 1993), attempts to transmit the virus with stable flies have been unsuccessful (Buxton et al., 1985; Weber et al., 1988; Freitas and Romero, 1991). It is unlikely that stable flies play a significant role in the transmission of BLV.

Rift valley fever

Rift Valley Fever is an acute zoonotic disease of ruminants and humans caused by the Rift Valley Fever Virus (RVFV; Bunyaviridae, *Phlebovirus*). It causes high mortality in newborn ruminants, especially sheep and goats, and abortion in pregnant animals. Humans are dead-end hosts. Endemic to sub-Saharan Africa, RVFV spread to Egypt in 1976 causing 200,000 human cases and 600 deaths (Chevalier et al., 2010) and in 2000 to the Arabian Peninsula (Balkhy and Memish, 2003). Mosquitoes and direct contact with infected fluids are the primary routes of transmission. However, biting flies including *Stomoxys* spp. and *Glossina* spp. can transmit the virus mechanically (Hoch et al., 1985). Their role in the epidemiology of RVF is probably small in endemic areas. Should the virus invade new territories such as Europe or the Americas, *S. calcitrans* could play a larger role.

West Nile encephalitis

West Nile is an acute encephalitis caused by the West Nile Virus (WNV). WNV is in the family Flaviviridae and normally transmitted by *Culex* mosquitoes. The virus was introduced to North America in 1999 resulting in an epizootic that progressed from east to west across the United States (Kramer and Bernard, 2001). In an unusual set of circumstances, a rookery of American White Pelicans was beset by WNV and stable flies. The stable flies fed heavily upon the sick and dying pelican chicks and were suspected of transmitting the virus among chicks (Johnson et al., 2010; Doyle et al., 2011).

Acquired immunodeficiency syndrome

Acquired immunodeficiency syndrome is caused by the Human Immunodeficiency Virus (HIV). Although Brandner et al. (1992) and Eigen et al. (2002) discuss the possibilities of *Stomoxys* being involved in the transmission of HIV, no observations of experimental transmission have been published. Analysis of epidemiological evidence concludes "There was thus no evidence of insect-borne HIV" (Goddard, 2018).

Porcine reproductive and respiratory syndrome (PRRS)

Porcine reproductive and respiratory syndrome is a globally important disease of swine caused by an arterivirus. The virus causes pneumonia in growing pigs, abortion in sows and loss of vigor. PRRS is easily transmitted among hogs within a herd by contact and exchange of fluids including saliva (Cho and Dee, 2006). Airborne transmission between isolated herds is suspected (Mortensen et al., 2002) possibly implicating insect vectors. Stable flies retain infective virus for up to 24 h after feeding on infected pigs (Rochon et al., 2015). However, attempts to transmit the virus to uninfected pigs by stable fly bites were not successful (Rochon et al., 2011). Stable flies do not appear to play any role in the transmission of PRRS.

Bacteria

Enteric bacteria

Unsurprisingly, given their association with animal wastes, enteric bacteria including *Campylobacter* spp. (Szalanski et al., 2004), *Enterobacter sakazakii* (Hamilton et al., 2003; Mramba et al., 2007), and mycobacteria (Fischer et al., 2001) have been observed in or

on stable flies. Stable flies do not congregate on and around human food as do house flies so probably do not play a large role in the contamination of foodstuffs. They may contaminate the coats of livestock and companion animals while feeding thus allowing for the ingestion of enteric pathogens when the hosts groom. The role of stable flies in the dissemination of these pathogens has not been established.

Dermatophilosis

Dermatophilosis is a pustular and crusting dermatitis in sheep, goats, cattle, horses, cats, and rabbits caused by *Dermatophilus congolensis*, a facultative anaerobic, branching Actinomycetes. Although *D. congolensis* has a worldwide distribution, most cases of dermatophilosis are observed in the moist tropics (Zaria, 1993). On cattle, lesions on the lower body and legs are usually attributed to tick bites or initial damage to the epidermis by vegetation. However, lesions on the backs have been attributed to flies (Stewart, 1972). Richard and Pier (1966) demonstrated transmission of *D. congolensis* from rabbit to rabbit with stable flies. However, Philpoot and Ezech (1978) found transmission from bovine to bovine by *Stomoxys* spp. to be rare and conclude that they are probably not primary vectors because of their predilection to bite on the lower body and legs whereas the dermatophilosis lesions were on the back of the cattle.

Anthrax

Anthrax is a serious infectious disease caused by *Bacillus anthracis*. The type of illness is dependent upon the method by which the pathogen entered the body. Four types of anthrax are recognized. Cutaneous, gastrointestinal, inhalation, and injection. The most common form is cutaneous which occurs when the bacteria enter the body through a skin abrasion or insect bite. Biting flies, especially horse flies, have been associated with anthrax since the earliest recorded outbreaks in the 1800s (Hugh-Jones and Blackburn, 2009). Several studies have documented the ability of *Stomoxys calcitrans* to transmit anthrax after feeding on an infected host (Schuberg and Kuhn, 1912; Schuberg and Boing, 1914; Mitzmain, 1914; Turell and Knudson, 1987). Epidemiological and spatial evidence support the involvement of biting flies in the transmission of cutaneous anthrax (Blackburn et al., 2014). However, the relative roles of horse flies and stable flies are unresolved. Horse flies appear to be the more efficient mechanical vector. However, stable fly numbers exceed those of horse flies by several fold in many regions. As for many pathogens and diseases stable flies overwhelming numbers may overcome their low vectoral efficiency.

Protozoa

Apicomplexa

Besnoitiosis

Besnoitiosis is a chronic and debilitating, emerging/expanding disease of cattle and other ruminants caused by the Apicomplexan protozoan *Besnoitia besnoiti*. *Besnoitia besnoiti* is closely related to *Toxoplasma gondii* and has a similar life cycle. Definitive hosts for *B. besnoiti* are felids; cattle are intermediate hosts. The majority of cases of besnoitiosis are in Africa. However, the disease is spreading to the Middle East, southern Asia, southern Europe, and even South America. *Besnoitia bradyzoites* can be transmitted mechanically by the bites of blood-feeding flies (Álvarez-García et al., 2013; Duvallet and Boireau, 2015). In France, the temporal pattern of *Besnoitia* transmission coincides with that stable flies (Liénard et al., 2011) and experimental transmission from chronically infected cattle to rabbits has been demonstrated (Sharif et al., 2019). At least in some locations, stable flies appear to play a primary role in the epidemiology of besnoitiosis.

Trypanosomatids

Trypanosomes are parasitic flagellate protozoans in the class Kinetoplastea, order Trypanosomatida, family Trypanosomatidae, genus *Trypanosoma*. Several species of *Trypanosoma* cause serious and debilitating disease in humans, livestock, and companion animals. Depending upon the species of *Trypanosoma* involved and the host, Trypanosomiasis go by many names. The Trypanosomes responsible for human Trypanosomiasis, also known as African Sleeping Sickness, *Trypanosoma brucei gambiense* and *T. b. rhodesiense* undergo cyclical development in their primary vector, *Glossina* spp. (tsetse flies). Several species of *Trypanosoma* can be transmitted directly from host to host via mechanical transmission as well. Stable flies have been implicated as vectors for several of those Trypanosomes. Of special interest relative to *Stomoxys* is the phenomenon of trypanosomiasis in the absence of *Glossina* spp. This is observed in parts of Africa where *Glossina* spp. are absent as well as in parts of Latin America and Asia.

Trypanosoma evansi (= *T. brucei evansi*)

Trypanosoma evansi is widely distributed in Saharan Africa, southern Asia, and South America (Radwanska et al., 2018) and is the etiological agent of Surra, a debilitating and economically important disease of equines, bovines, and camelids (Aregawi et al., 2019). *Trypanosoma evansi* is a form of *Trypanosoma brucei* that lost functional kinetoplasts and as a result, the ability to develop cyclically in *Glossina* spp. *Trypanosoma evansi* is therefore dependent upon mechanical transmission for movement from host to host. Stable flies and horse flies (Tabanidae) have been implicated as the primary vectors of *T. evansi* (Luckins, 1988; Lun et al., 1993; Desquesnes et al., 2008). Stable flies have been associated with the transmission of *T. evansi* in time and space (Desquesnes et al., 2008; Rodríguez et al., 2014). Experimental demonstrations of transmission of *T. evansi* by *S. calcitrans* however are scant. Bouet and Roubaud (1912) demonstrated transmission in several experiments and indicated that *Stomoxys* spp. play a major role in the epidemiology of Surra. However, their experiments lacked controls and some of the rigor expected in more recent studies. Sumba

et al. (1998) demonstrated transmission with *Stomoxys niger* and *S. taeniatius*, but *S. calcitrans* was not included in their study. Desquesnes et al. (2013) discuss the biological and epidemiological properties of *Stomoxys calcitrans* that would support their involvement in the transmission of *Trypanosoma evansi*, but do not demonstrate experimental transmission. Ngeranwa and Kilalo (1994) were unable to transmit *T. evansi* between goats or camels with *S. calcitrans*. Failure of laboratory transmission studies should not be taken as strong evidence that *S. calcitrans* is not involved in the transmission of *T. evansi* because most such studies involve relatively small numbers of flies/bites. In the field, animals can be bitten by 10- to 100-thousand flies or more per day during severe outbreaks. Such numbers can overcome low odds. Additional research is needed to elaborate the role of *Stomoxys* spp. and specifically *S. calcitrans*, in the epidemiology of Surra.

Nagana

Nagana is an acute or chronic disease caused by several species of trypanosomes. *Trypanosoma congolense* causes a chronic form of the disease while *T. brucei brucei* and *T. vivax* cause an acute form. Primarily, these trypanosomes are cyclically transmitted by *Glossina* spp. However, *T. congolense* and *T. vivax* can be transmitted mechanically by Tabanids and Stomoxines. This has allowed them to expand their range beyond that of *Glossina* spp. *Trypanosoma congolense* is limited to sub-Saharan Africa while *T. vivax* has expanded its range to much of South and parts of Central America (Radwanska et al., 2018). The relative importance of Tabanids and Stomoxines in the transmission of *T. congolense* and *T. vivax* is unclear. Experimental mechanical transmission of *T. congolense* and *T. vivax* by Tabanids has been demonstrated (Ferenc et al., 1988; Raymond, 1990; Otte and Abuabara, 1991; Desquesnes and Dia, 2003, 2004). Sumba et al. (1998) demonstrated mechanical transmission of *T. congolense* by *Stomoxys niger niger* but *S. calcitrans* was not included in their study. Transmission of *T. vivax* (= *T. cazalboui*) by mixed species of *Stomoxys* was reported by Bouet and Roubaud (1912) but similar efforts by the same authors to transmit *T. congolense* (= *T. dimorphon*) with *Stomoxys* failed. Santos-Silva et al. (2004) reported that Serra-Freire and Rezende (1988) had successfully transmitted *T. vivax* mechanically with *S. calcitrans*. In conclusion, experimental data supporting the involvement of *S. calcitrans* in the transmission of *T. congolense* and *T. vivax* are thin. However, given the very high infestation levels of *S. calcitrans* observed in some locations and their propensity for interrupted feedings, their role in transmitting these pathogens cannot be ruled out even if their efficiency is very low and difficult to replicate in the laboratory.

Leishmaniasis

Leishmania spp. are the etiological agent for several diseases of humans and animals including cutaneous, visceral and mucocutaneous forms of the disease. *Leishmania* spp. are normally transmitted cyclically by phlebotomine sand flies. However, in some urban and peri-urban environments, where phlebotomine sand flies are rare or absent, it is possible that other biting flies may be responsible for mechanical transmission of *Leishmania* spp. Coelho et al. (2016) observed viable *Leishmania* spp. in field collected tabanid flies, but not in *S. calcitrans*. Berberian (1938, 1939) documented that *S. calcitrans* were able to transmit *Leishmania tropica* immediately after an interrupted meal on an open Oriental sore. These results were duplicated by Lainson and Southgate (1965) with *Leishmania mexicana*.

Nematodes

Habronemiasis

Horse stomach worms *Habronema* spp. infect the stomachs of horses. Adult worms release eggs which pass out with the feces. Eggs hatch soon after being excreted and the first instar larvae are eaten by fly larvae in the manure. The worms molt twice in the fly larvae and develop into infective L3 larvae by the time the adult fly emerges. The L3 escapes the fly host while it is feeding, usually around the nose or lips of the definitive host. L3 larvae are ingested by the host, pass to the stomach where they mature and complete the cycle (Pugh et al., 2014). Stable flies are the intermediate host for *Habronema microstoma* and house flies for *H. muscae* (Traversa et al., 2008). If the L3 nematode larva are deposited near a wound or the eyes, they are unable to develop into adults and continue to migrate in the skin causing inflammation and a condition referred to as "summer sore." This is the only situation where stable flies are considered biological or cyclical hosts of a pathogen.

Biology and ecology

Taxonomy and phylogeny

Stable flies are members of the subfamily Muscinae, tribe Stomoxyini of the Dipteran family Muscidae (Zumpt, 1973). The genus *Stomoxys* includes 18 species most of which are endemic to Africa with several species ranging to the Indian subcontinent and southeast Asia (Zumpt, 1973). *Stomoxys calcitrans* is cosmopolitan, having accompanied human mediated introductions of livestock around the world. As currently recognized, the genus *Stomoxys* is considered paraphyletic because of the segregation of *Prostomoxys saegerae* (Zumpt) (Dsouli et al., 2011).

Morphology

Adult stable flies are approximately the same size as house flies, 5–8 mm long, and generally of similar appearance. They can be differentiated from house flies by the presence of a rigid proboscis projecting forward from the head (Fig. 1). The thorax is grey with

Fig. 1 *Stomoxys calcitrans* (photo credit: Stephen Ausmus, USDA Agricultural Research Service). <https://www.ars.usda.gov/oc/images/photos/nov12/d2620-1/>.

four longitudinal dark stripes. The abdomen is grey with darker spots medially on the base of segments 3, 4, and 5 and lateral on the apex of segments 3, 4 and sometimes 5 (Zumpt, 1973). Males and females are similar with the eyes of males well separated and only slightly larger than those of females.

Stable fly eggs are whitish and ≈ 1.0 mm long and 0.3 mm wide. Eggs are slightly curved, convex on the ventral side and concave on the dorsal side. Two parallel lines of dehiscence are visible on the dorsal side (Parr, 1962; Salem, 2012).

Stable fly larvae are typical of muscoid fly maggots. Mature, third instar, larvae are 10–11 mm long and creamy white. Stable fly larvae can be differentiated those of house fly by the shape and relative position of the posterior spiracles. In house flies, the posterior spiracles are semicircular and proximate with the button located near the inner margin. In stable flies, the posterior spiracles are separated by more than the diameter of a spiracle, semi-triangular in shape, and the button is located near the center of each.

Stable fly puparia are 6–7 mm long and often slightly more reddish brown than those of house flies which are usually a darker brown. The integument of the puparia is that of the third instar larva. Therefore, larval morphological traits, especially the spiracular plates, can be used to differentiate stable fly puparia from those of house flies.

Life cycle

As all dipteran flies, stable flies are holometabolous, going through egg, larva, pupa, and adult stages during their development. Females lay up to approximately 150 eggs directly on the developmental substrate. Eggs are usually laid in small groups of several to 20 or more dispersed in small crevices and irregularities on the surface of the substrate. Under optimal conditions, 25–30 °C, eggs hatch ≈ 24 h after oviposition. Larvae are vermiform and progress through three instars, growing from ≈ 1 mm to ≈ 11 mm in 7–8 days. Mature larvae molt into coarctate puparia followed by a true pupal molt within the puparia ≈ 1 day later. Adults eclose 7–10 days after pupariation. The duration of development from egg to adult is 19–20 days. Under suboptimal conditions, temperatures between 15 °C and 20 °C, development can take 70 or more days (Parr, 1962; Lysyk, 1998; Salem et al., 2012; Florez-Cuadros et al., 2019). Stable flies are not known to have diapause or freeze tolerant stages (Greene, 1989).

Stable fly larvae develop in a broad variety of fermenting vegetative materials (Simmons and Dove 1941, 1942; Siverly and Schoof 1955; Hafez and Gamal-Eddin 1959; Sutherland 1978; Campbell and McNeal 1979; Williams et al., 1980; Hall et al., 1982; Cook et al., 1999, 2018; Solórzano et al., 2015), often contaminated with animal feces and urine. Larvae are most likely to be found in moist, slightly alkaline substrates with high levels of ammonium and coliform bacteria (Talley et al., 2009; Friesen et al., 2016). Although stable fly larvae can develop in pure, fresh bovine feces in the laboratory, they are rarely found in such in the field (Hogsette et al., 1987).

Blood feeding, digestion and ovarian development

Both male and female adult stable flies bite vertebrate hosts and feed upon blood. They will feed upon virtually any available mammal and, under unusual circumstances, birds (Johnson et al., 2010). Because their bites are quite painful, they are more likely to feed upon larger, less agile, and more docile animals such as cattle. They will rarely feed upon humans in the vicinity of livestock, but, can be severe nuisances for humans in the absence of livestock in urban or recreational areas. It takes 2–4 min for a stable fly to imbibe a full blood meal. Three fourths of feedings are interrupted, either by host defensive behaviors or by other flies, (Schofield and Torr, 2002) causing flies to initiate feeding multiple times and, often, on multiple hosts.

Males require a blood meal in order to produce seminal fluid components (Anderson, 1978). Females require multiple blood meals prior to mating (Anderson, 1966) and subsequent blood meals to develop their first batch of ≈ 150 eggs. Blood meals are usually taken at daily intervals when hosts are available (Anderson and Tempelis, 1970; Harris et al., 1974). Females can develop additional batches of eggs every 3–5 days with continued blood feeding. Both sexes bite and take blood meals throughout their adult life. In the absence of hosts, both sexes can feed on nectar for sustenance (Jones et al., 1992; Taylor and Berkebile, 2008). Although providing energy for flight and basic metabolism, nectar does not support mating or ovarian development. Adults can live up to 4–6 weeks; however, in the field, few survive more than 5–10 days.

Stable flies ingest ≈ 11 μ L of blood in a blood meal (Salem et al., 2012). Males ingest less and the amount ingested by females is dependent upon their stage of ovarian development. The first, second and third blood meals, are larger and take up to 4 days to be digested. However, females continue to feed daily even though previous blood meals are not completely digested. The final blood

meal prior to oviposition may be one-half the volume of blood relative to prior blood meals and digested within 24 h (Anderson and Tempelis, 1970). Virgin females continue to take blood meals and ovarian development proceeds to the fully gravid stage, however, they will not oviposit until mated (Venkatesh and Morrison, 1980).

Mating

Both male and female stable flies begin mating 2 days after eclosion. Prior to their first blood meal, males appear to be uninterested in attempting to mate and females are not receptive to mating. Males perch in sunny locations, often on feed bunks or fence rails, and dart out and grab passing flies, or even fly sized pebbles. Long chain methylated hydrocarbons on the cuticular surface of the female act as contact pheromones, stimulating the male to attempt to mate (Sonnet et al., 1977). If the target is not a female stable fly, the male will return to a perch, often the same one as previously occupied, to await another opportunity. If the target is a receptive female stable fly, the couple alight and remain in copula for 4–6 min (Parr, 1962). Males can inseminate up to 10 females, while females mate only once (Harris et al., 1966).

Dispersal

Stable fly dispersal and the related topic of mode of recolonization of temperate regions in the spring remain unsettled, probably because they vary relative to regions and possibly localities. Stable flies are strong fliers with the ability to disperse long distances. Flight mill studies indicate they can fly nearly 30 km per day (Bailey et al., 1973). Observations of stable flies many kilometers from shore on large bodies of water such as Lake Michigan and coastal waters attest to their flight abilities. Hogsette and Ruff (1985) recaptured several stable flies marked 160–225 km from the recapture sites on the Gulf Coast of Florida. However, the number of recaptures was small (7) and few intermediate distance traps were included in the study such that median, population level, dispersal distances could not be calculated. Studies looking at larger numbers of flies with denser trap arrays and abundant hosts observed median distances to recapture <1–1.6 km (Bailey et al., 1973; Gersabeck and Merritt, 1985; Taylor et al., 2010). In New Zealand, Todd (1964) noted that few stable flies were observed more than 1 mile (1.6 km) from larval developmental sites. Stable flies appear to move only as far from their natal site as needed to find hosts and then congregate near the hosts (Todd, 1964; Bailey et al., 1973).

Several workers have postulated that stable flies move long distances at high altitudes with weather systems (Hogsette and Ruff, 1985; Jones et al., 1999; Isard et al., 2001). This hypothesis is supported by observations of large populations of stable flies in localities lacking identified developmental habitats (Broce, 1993). However, stable flies are seldom collected on traps placed higher than 1.5–2 m above ground level (Williams and Rogers, 1976). Direct evidence, including the collection of stable flies flying at high altitudes, is needed to support high altitude migration of stable flies.

Prevention and control

Management of stable fly populations has proven to be a difficult task. The most successful programs have involved an Integrated Pest Management (IPM) approach involving cultural, mechanical and biological control methods in addition to insecticides. Insect control is most effective when the target is concentrated and immobile (Novak et al., 2010). For stable flies, the larval stage is the preferred target. Sanitation should be the primary component of stable fly management (Thomas et al., 1996). Sanitation involves the removal and proper disposal of vegetative waste and residues, especially those contaminated with animal waste, proper storage of silage and other animal feed stocks, timely removal of animal and feed wastes from pens and corrals. Unfortunately, sanitation is often not logistically feasible. The quantities of waste involved can be extremely large, for instance post-harvest pineapple residues can exceed 250 metric tons per hectare, the time frame very short, stable flies can go from egg to adult in just over 1 week, and disposal options are limited. In addition, stable fly larval developmental sites are ephemeral and often difficult to identify prior to adult emergence, especially in pasture settings (Broce et al., 2005). However, without sanitation as a component of an IPM program to limit the resources for developing flies, other methods are doomed to failure.

The most promising biological control option for stable flies is represented by the inundative release of parasitoid wasps. Pteromalid wasp in the genera *Muscidifurax* and *Spalangia* have been employed most frequently. Natural populations of native parasitoids are unlikely to reach population levels adequate to reduce stable fly populations to below the economic threshold, especially in pasture environments (Rutz, 1986). Results of parasitoid releases on stable fly populations have been mixed with the most success in defined habitats such as dairies and little success in open habitats such as pastures (Machtinger and Geden, 2018).

Mechanical approaches to stable fly management involve manipulating or modifying developmental substrates to reduce their suitability for larvae to complete development to adulthood. Covering or enclosing silage can effectively keep flies from laying eggs and adults from emerging into the environment. Likewise, covering manure piles can keep adult flies from emerging. Mechanical control has been used in Australia to bury vegetable crop residues and compress the overburden to keep adult stable flies from emerging (Cook et al., 2020). Burying pineapple residues at least 1 m deep has been used for stable fly control in Costa Rica, but the cost ≈\$4000 US per hectare is prohibitive.

Chemical control of stable fly larvae in the developmental substrates is difficult because microbial activity in the substrates rapidly breaks down most insecticides. Two classes of growth regulators, triazines and benzoylureas, can provide 8–12 weeks of

stable fly control in developmental substrates (Taylor et al., 2012a, 2014). Novaluron (a benzoylurea) is used on pineapple plants prior to chopping for field renovation in Costa Rica to control stable flies developing in the chopped plant residues.

Control of adult stable flies is difficult because the flies spend little time on the host, feed primarily on the lower legs where insecticides and repellants are easily washed off by wet grass, and the flies can move relatively long distances in search of hosts. Few products are registered for use against stable flies on food animals such as beef and dairy cattle because of the threat of residues in food products. Pyrethroids are the most commonly used class of insecticides used for stable fly control. However, pyrethroid resistance is becoming a greater and greater problem with some populations being fully resistant (Olafson et al., 2019). Long lasting stable fly repellants such as coconut fatty acids (Zhu et al., 2018) are in the developmental and formulation stages and may offer promise for reducing the impact of stable flies on livestock.

Introduction

Within the Oestroidea super-family, larvae of flies belonging to the families Oestridae, Calliphoridae and Sarcophagidae feed on dead or living animal tissues, therefore developing from first to second and third instar larvae (L1, L2 and L3). In their attitude in feeding on and infesting alive tissues, some of these larvae cause infestations known as myiasis (Colwell et al., 2006). While Calliphoridae and Sarcophagidae larvae may feed of dead or living tissues, therefore causing facultative myiasis and being also of forensic importance, the Oestridae includes flies which larvae cause only obligatory myiasis. Oestridae contains a large number of species, about 150, whose larvae parasitize a wide range of hosts, from mice to elephants. They display a high degree of host specificity and their biological life cycle may be extremely complex as a result of a longlasting adaptation to the host (Otranto, 2001). The four sub-families of medical and veterinary importance are Gasterophilinae, Oestrinae, Hypodermatinae and Cuterebrinae. Within the Gasterophilinae, the most important genus, *Gasterophilus*, consists of eight species, three of which are worldwide distributed. The sub-family Oestrinae includes nine genera and 34 species (known as nostril flies), the sub-family Cuterebrinae includes six genera and 83 species and the sub-family Hypodermatinae includes six species of the genus *Hypoderma* which are of major veterinary concern (Russell et al., 2013). In the following, we summarize the epidemiology, life cycle, the medical and veterinary importance as well as the control of the main species belonging to the family Oestridae.

Hypodermatinae

Within the sub-family Hypodermatinae and the genus *Hypoderma*, six species are of veterinary importance. All these larvae cause dermal myiasis and the most studied are *Hypoderma bovis* and *Hypoderma lineatum*, also known as cattle grubs, which have an important impact on cattle productions and a widespread distribution in the northern hemisphere (Colwell et al., 2009). Other species affect roe deer (*Hypoderma diana*), red deer (*Hypoderma actaeon*), reindeer (*Hypoderma tarandi*) and yak (*Hypoderma sinense*) and have been occasionally detected in other animal species, including humans, as subdermal and internal ocular myiasis. Another species within the Hypodermatinae subfamily is *Przhevalskiana silenus*, which causes the goat warble fly infestation, a myiasis characterized by the presence of warbles under the skin of the back and flanks of goats (Fig. 1).

Adults are typically bumble-bee-like flies with reddish yellow hairs at the posterior extremity of the abdomen and have rudimental mouthparts. The morphological identification of *Hypoderma* is mainly carried out on L3, since this is the most common developmental stage retrieved by practitioners and veterinary inspectors from live and slaughtered animals in typical warbles under the skin of the infested animals (Fig. 2). The morphological differentiation of L3 is not difficult, but can sometimes be troublesome because *Hypoderma* spp. have similar ecological, biological and morphological features. Indeed, *Hypoderma* flies are frequently present in the same environment and their larvae may sometimes share hosts (e.g. *H. bovis* and *H. lineatum* cattle, *H. diana* and *H. actaeon* red deer). For example, although host specificity is generally high, *H. bovis*, *H. lineatum* and *H. sinense* have been collected from yaks (Huang et al., 1987; Otranto et al., 2004a, 2005a). Accordingly, some *Hypoderma* species share epitopes of antigens secreted during larval migration inside host tissues (Boulard et al., 1996a).

The mature L3 is large (30 mm in length) presenting body segments with tiny spinulation (differently from Oestrinae larvae, which have dark transverse dorsal bands and transverse rows of spines on the ventral surface of each segment) and flat spiracular plates, both structures different in presentation (Otranto et al., 2003). Microscopic differences among *Hypoderma* spp. is based on

Fig. 1 Larva of *Przhevalskiana silenus* in the subcutaneous tissue of a goat. Photo: Otranto D.

Fig. 2 *Hypoderma lineatum* warbles under the skin of infested cattle during the early spring. Photo: Lia RP.

the pattern and morphology of spines on the cephalic and thoracic segments, by spine patterns on the tenth abdominal segment, and by morphology of the spiracular plates (Colwell et al., 1998; Otranto et al., 2003). The morphological differences above are also supported by the molecular characterization of the most variable region of the *cytochrome oxidase I* gene of these species, which showed to be a useful marker for the molecular identification and phylogenesis of this group of insects (Otranto et al., 2003).

As soon as they emerge, the females lay eggs (300–650) on the host's hair with adhesive material. While *H. bovis* females lay single eggs per hair on the rump and upper parts of the hind leg of cattle causing gadding, *H. lineatum* females lay 7–10 eggs in line along a single hair on the legs, which do not disturb the host. After hatching, the L1 penetrates the skin using collagenolytic enzymes secreted from the blind midgut (Boulard et al., 1996a). These enzymes are extremely immunogenic (i.e. they elicit an immunoreaction which is important for an early serological diagnosis) and enables larvae to migrate throughout the host's body for several months until they reach their final localization on the back of the host. During the winter months, migrating L1s of *H. lineatum* are found within the wall of the esophagus (Fig. 3), whereas those of *H. bovis* in the epidural fat of the spinal canal (the latter probably migrate along nerve trunks or through muscles). *Hypoderma sinense* presents a migration in the host body, similar to that of *H. lineatum* (Otranto et al., 2006a). Following this migration, L1s move to the host's back under the skin where they form nodules, also known as warbles. In this site, the L1 develops into L2 and L3 and release collagenolytic enzymes accumulated in their gut, piercing the skin and form a hole, allowing the breathing (Fig. 4). Full mature larvae drop to the ground, where they move actively, pupate and develop to adult fly in 3 to 10 weeks, depending upon environmental conditions (Fig. 5). The life cycle of larval *P. silenus* is exclusively subcutaneous without internal migration (Otranto and Puccini, 2000).

Fig. 5 Mature third stage larvae of *Hypoderma lineatum* drop in the environment. Notice the dark coloration, which indicates the larva is ready to pupate. Photo: Lia RP.

Distribution and biology

Reports on clinical infestation of cattle, serum and milk serology surveillance studies, parasiticide efficacy studies and/or description of human cases published over the past years provide evidence that populations of *Hypoderma* spp. are still present in cattle in North America including Canada and the United States, as well as in Europe, e.g. in Portugal, Spain, France, Italy, Belgium, Switzerland, Germany, Poland, Slovakia and Estonia (Minář, 2003; Haine et al., 2004; Otranto et al., 2005a; Zygutiene et al., 2006; Panadero et al., 2007; Colwell, 2013; Rehbein et al., 2013). In addition, bovine hypodermosis is also reported in several countries in eastern and south eastern Europe including Belarus, Russia, Romania, Serbia, Bosnia and Herzegovina, Kosovo, Albania and Greece (Papadopoulos, 2004; Otranto et al., 2005b; Gorcea et al., 2011), and it is still abundant at high levels in resource-limited countries in northern Africa and Asia (Otranto et al., 2004a; Guan et al., 2005; Saidani et al., 2011; Dehghani et al., 2012; Yadav et al., 2013; Jaiswal et al., 2016).

Adult *H. lineatum* occur from late March to the end of May, whereas *H. bovis* from June to mid-September. Soon after eggs laying, L1s undertake migration (for *H. lineatum* from April until September) and can be found in the esophagus during the winter months with warbles appearing on the host's back from January to April. Therefore, mature L3s leave the host to pupate from March to early May (Colwell et al., 2006). The biological cycle of *H. bovis* is slightly delayed of some months also because they usually occur in northern, colder, regions. *Hypoderma sinense* infects cattle and yaks in China (Otranto et al., 2004a), where prevalence of infestation by *H. bovis* and *H. sinense* may be extremely high (up to 98–100% of animals and intensities exceeding 400 warbles per animal). According to the timing of this life cycle an early serological diagnosis of infestation (ELISA) throughout September–November (when warbles are still undetectable by palpation) and subsequent treatment strategies are advised (Otranto et al., 2016). Adults fly at temperatures above 18 °C, surviving for 3–5 days only, for mating and laying eggs (they have not a mouthpart for feeding). *Hypoderma diana* parasitize deer throughout Europe and Asia living in several different ecological zones where their hosts are distributed. The larvae reach the skin on the host's back where they develop into swellings warbles, developing in cysts containing purulent fluid. *Hypoderma tarandi* (the reindeer warble fly) infests reindeer/caribou in arctic and sub-arctic regions of northern Europe, North America and Russia. Its life cycle is similar to that of other species of this genus with the exception of female laying eggs (500–700) to the undercoat and the larvae then burrow into and under the skin during July–August without major migration in the body of the animals. During September–October, mature larvae form a warble, inducing damage to hides and leading to economic losses. As for almost all *Hypoderma* species the intensity of infection and prevalence are higher in younger animals, possibly as a consequence of the lack of acquired resistance (Lysyk et al., 1991).

Larvae of *P. silenus* penetrate the skin and develop to L2 and L3 nearby, without any migration in internal organs or in the subcutaneous tissue (Otranto and Puccini, 2000).

Medical and veterinary importance and control

Although bovine hypodermosis does not induce significant mortality and morbidity, this infestation affects the productivity and welfare of animals resulting in considerable losses to the livestock industry arising from a number of causes (Hall and Wall, 1995; Reist et al., 2002; Hassan et al., 2010). The importance of myiasis caused by *Hypoderma* spp. to livestock production and their distribution has been greatly reduced over the decades as a consequence of eradication campaigns in many countries and of the systemic use of macrocyclic lactones (Lia et al., 2019). Nonetheless, economic losses due to *Hypoderma* spp. still occur in some areas (e.g. southern Mediterranean regions, eastern Europe and China) and they are also at risk of reintroduction due to the spread in organic farms and the limited use of systemic endo-ecto-parasiticides (Colwell et al., 2009). Beyond the disturbance caused by ovipositing flies to grazing cows, reduction in weight gain and milk production is also a consequence of larval migration in the body of the animals. In addition, damage of the hide caused by holes formed by the L3s reduce the hide value in the leather industry (Hassan et al., 2010).

The presence of *Hypoderma* larvae may be detected by palpation of the warbles on the animals' backs (clinical parasitological examination) during the spring and summer months or by examination of subcutaneous tissues (Fig. 2) and internal organs of carcasses (post mortem examination). Some ELISA tests (Boulard et al., 1996a,b) have been used in many countries for the serodiagnosis of the disease. Anti-*Hypoderma* antibodies persist in infected cattle for 3–4 months after the L3s fall from their backs to the ground and antibody levels peak between November and March in Europe, making these the optimum months for testing and for achieving an early diagnosis of hypodermosis before the formation of warbles (Pruett and Barret, 1985). Testing commercial milk for antibodies has been shown to be effective for detecting the presence of hypodermosis in cattle, especially in those countries for which no data on this disease are available (Otranto et al., 2001). Cross-reactivity between *H. lineatum* antigen and anti-*P. silenus* antibodies allowed to prepare an ELISA for the detection of goat warble fly infestation demonstrating an antibody kinetics in naturally infested goats similar to that recorded in *H. lineatum*-infested animals (Otranto et al., 1999).

Human infestation by *Hypoderma* spp. occurs sporadically as ophthalmomyiasis or subdermal warbles and even skin allergies (Panadero-Fontán and Otranto, 2015). Infestation occurs in people who are closely associated with livestock or reindeer flocks as reported in case series in Norway (Kan et al., 2013). In poor socioeconomic settings of China, the infestation may occur in 0.4–7% of cattle and yak farmers.

Larvae of *Hypoderma* spp. are highly susceptible to systemically active organophosphates and macrocyclic lactones. These chemicals should be administered between September and October, but not later (mid-November and mid-March), in order to avoid anaphylactic reactions to toxins released by dead larvae, while migrating in the spinal canal or esophagus. Macrocyclic lactones, even when used at minimum dosage are highly effective as demonstrated in systemic campaigns which successfully

eradicated cattle hypodermosis in large areas of Central Europe (United Kingdom, Eire, Denmark and the Netherlands). However, the risk of reintroduction is constant. In a pilot study carried out in southern Italy on 9939 cattle bred in an area with a high prevalence of cattle hypodermosis, the use of moxidectin at 0.5% pour-on and 1% injectable formulations demonstrated an efficacy of 99.9% and 100%, respectively, showing the real opportunities of national programs for eradicating warble fly infestation (Otranto et al., 2005c). Macrocytic lactones administered with the feed may be used to eliminate oestrids from farmed deer.

Oestrinae

Larvae of the sub-family Oestrinae develop in the nasopharyngeal cavities of ungulate mammals, and occasionally infest human beings causing ophtalmomyiasis (Hall and Wall, 1994). The most important species are *Oestrus ovis* in sheep and goats, *Rhinoestrus purpureus*, in equids, *Cephalopina titillator* in camels, *Cephenemyia trompe* in reindeer, and *Tracheomyia macropi* in red kangaroo. Larvae of all these flies are firmly attached to the nasal mucosa through well-developed mouth-hooks, whereas the adults, without mouthparts, are short-lived.

While L1s of *O. ovis* (about 1 mm long) have gently curved mouth-hooks and terminal spines arranged in two groups (Fig. 6), mature L3s (about 25 mm long) have dark transverse bands dorsally and transverse rows of spines ventrally on each segment. After the development in the uterus, L1s are projected by female flies into the nose or eye of the proper host (e.g. *O. ovis* ejects about 20 larvae into the nasal cavities of sheep and goats), from where they move into the frontal and/or maxillary sinuses, developing until L3 (Fig. 7). Developed larvae, usually of a brownish color, migrate back toward the nasal cavities to be expelled by sneezing or coughing into the environment where they pupate before the next generation of adults emerge. *Rhinoestrus purpureus* larvae may localize into the pharynx of the host or even in the trachea.

Fig. 6 First stage larvae of *Oestrus ovis* (about 1 mm long) collected on the nasal mucosa soon after being projected by female fly. Note the tiny spinulation on the body segments and the two mouth-hooks which are important for the migration on the nasal mucosa. Photo: Lia RP.

Fig. 7 Mature third stage larvae of *Oestrus ovis* in the nasal cavities and sinuses. Photo: Lia RP.

Distribution and biology

Oestrus ovis has a worldwide distribution in the Palearctic ecoregion. Adults fly during summer causing disturbance in flocks, with sheep typically keeping their heads toward the ground in order to avoid them. Two fly generations usually occur per year in the northern hemisphere, with adults emerging in late spring, mate and ejecting larvae into the eyes or nose of the hosts. L1s develop rapidly and mature until L3s to leave the host in July and August. Adults may fly in autumn, larvipositing in September and October with the overwintering of L1s within the host. The biological life cycle may start again during early spring with a new generation of flies emerging from the pupae in June.

Infestation with *O. ovis* is commonly recorded in flocks where treatments are not regularly performed. Larvae may cause irritation of the mucosa, and mucopurulent discharge and impaired respiration, whereas, adult *O. ovis* causes sheep annoyance, leading to loss of grazing time (Papadopoulos et al., 2006). Late summer and/or winter treatment with macrocyclic lactones, such as ivermectin, is extremely efficacious with a clear reduction in nasal discharge and increased weight gain.

Cephenemyia spp. larvae develop in deer causing nasal discharge, sneezing, coughing and restlessness. Females eject live L1s in the nostrils of the hosts and after moving to the pharyngeal and nasal cavities they mature and migrate to the anterior pharynx before leaving the host as L3s to pupate in the environment.

Larvae of the genus *Rhinoestrus* localize in the throat region, at the base of the tongue, in the pharyngeal cavity and in the turbinates of equines. There is one generation per year and the female ejects larvae in batches at a time into the nostrils or eyes of a horse. L1s may remain in the nasal cavity for many months before moving to the sinuses to complete their development. Of the 11 species described, four are restricted to equines and seven to a wide range of wild animals (e.g. giraffe, warthog, bushpig and antelope). The most common species is *R. purpureus*, which parasitizes horses, donkeys and their crossbreeds. Both *R. purpureus* and *R. usbekistanicus* are diffuse in southern Europe with prevalence up to 21% in native horses and intensity rate as high as 65 larvae per host (Otranto et al., 2004b). L3s of the two species above are differentiated morphologically based on the shape of spiracular plates and the rows of spines on the dorsal view of the third larval segment (Otranto et al., 2005e) which is complete in *R. purpureus* (Fig. 8A) or narrowly interrupted medially in *R. usbekistanicus* (Fig. 8B).

Within the genus *Cephalopina*, *C. titillator*, the camel nasal bot fly, is extremely diffuse in dry parts of the Palearctic and Oriental ecoregions, and Australia with a prevalence of up to 90% in camel herds (Sazmand and Joachim, 2017). Due to their large size and presence of strong spinulation (Fig. 9), larvae may cause considerable irritation, breathing difficulty and lesions, which provide a suitable environment for pathogen proliferation and, eventually, pneumonia.

Medical and veterinary importance and control

For all the Oestrinae, adult fly activity and larvae depositing disturb animals, leading to a loss of grazing time with a reduction in weight gain. The parasitic rhinitis caused by the larvae is usually characterized by a mucoid nasal discharge, which may also be hemorrhagic. This could lead to histopathological changes with infiltration of inflammatory cells and squamous metaplasia and allergenic reactions provoked by molecules excreted/secreted by the larvae (Angulo-Valadez et al., 2011). Clinical signs of infestation include mild discomfort, nasal discharge, sneezing, nose rubbing or head shaking. Macrocyclic lactone endectocides are highly effective with treatments given, for *O. ovis*, twice a year (i.e. at the beginning of summer to kill newly acquired larvae, and in midwinter to kill any overwintering larvae). Infestation of Oestrinae larvae occasionally occurs in humans where they cause

Fig. 8 Third stage larvae of *Rhinoestrus* spp. characterized by complete rows of spines on the dorsal view of the third larval segment (A) (*Rhinoestrus purpureus*) or narrowly interrupted medially (B) (*Rhinoestrus usbekistanicus*). Photo: Otranto D.

ocular myiasis and even blindness. External infestation can be managed by physical removal of the larvae, but management of internal infestation requires expert assistance (Panadero-Fontán and Otranto, 2015).

Gasterophilinae

The subfamily Gasterophilinae includes flies whose larvae infest the gastrointestinal and pharyngeal mucosa of their hosts, causing inflammation, sloughing of the tissue and ulcerations. The genus *Gasterophilus* is the most important and it consists of eight species infesting equids, and *Gyrostigma* and *Cobboldia*, infesting rhinoceroses and elephants, respectively (Hall and Wall, 1994). Human cases with creeping dermal and oral/ocular infestations have been only occasionally reported.

Among *Gasterophilus* spp., *Gasterophilus intestinalis* is the most prevalent and widely distributed species in horses followed by *Gasterophilus nasalis*, *Gasterophilus haemorrhoidalis*, *Gasterophilus pecorum* and *Gasterophilus inermis*. The same species may also parasitize zebras. *Gasterophilus intestinalis* is the most important horse bot fly in Europe, the United States and Australia. In some countries of the Mediterranean basin, *G. intestinalis*, *G. nasalis*, *G. inermis*, *G. pecorum* and *G. haemorrhoidalis* occur in sympatry in free-grazing horses (Otranto et al., 2005d). The presence in some regions of southern Europe of an unusually large number of different species of bot flies has suggested a high degree of oestrid biodiversity in this area. The many factors that can influence parasitic species composition (e.g. host and parasite genetics, relationships with their hosts and environment and animal management) include the movement of domestic animals in association with migrating human populations in southern Europe over thousands of years (Otranto et al., 2006b).

While the adult of these insects are robust dark, large flies (10–15 mm in length). The larvae are armed with spines with robust mouth-hooks (Colwell et al., 2006). In the stomach, intestine or pharynx, mature L3s (16–20 mm) are cylindrical, reddish with two rows of spines anteriorly on most segments (*G. nasalis* has only one row). Number, shape and distribution of spines on the larvae metamers represent differential characters (Colwell et al., 2007).

Distribution and biology

Flies lay eggs (Fig. 10) on the host (i.e. *G. haemorrhoidalis* on the hairs around the lips, *G. nasalis*, *G. inermis*, and *G. intestinalis* on the intermandibular space below the jaws, on the cheeks and on the front legs, respectively) and the newly hatched L1s penetrate the tissues of the oral cavity and throat to migrate to the different tracts of the host's intestinal apparatus where they develop to L2 and L3 while attached to the mucosa. The localization of L2s and L3s varies according to *Gasterophilus* spp. For instance, *G. pecorum* resides on the soft palate and at the basis of the tongue, whereas *G. intestinalis* in the cardiac region of the stomach (Fig. 11). Moreover, *G. nasalis* locates in the pyloric region of the stomach and in the first portion of the duodenum, whereas *G. haemorrhoidalis* in the fundus of the stomach and the duodenum, and L3s in the rectal mucosa. Finally, also larvae of *G. inermis* reside in the rectal mucosa. There, the L3s stay for several months before passing into the environment with the feces and pupate. One or more generation of *Gasterophilus* spp. may occur every year in northern temperate or tropical regions, respectively.

According to their biological life cycle, infestation occurs at any time of the year with very high prevalence of infestation in horse heard living in the same area, with a high intensity of infestation (i.e. up to 738 per horse, of which 689 *G. intestinalis* in the stomach, 39 *G. nasalis* in the duodenum and 10 *G. inermis* in the rectum, in a survey conducted in southern Italy (Otranto et al., 2005d).

Fig. 11 *Gasterophilus intestinalis* third-stage larva firmly attached to the esophageal portion of the stomach. Photo: Lia RP.

Medical and veterinary importance and control

Due to their well-developed mouth-hooks, L2s and L3s of *Gasterophilus* spp. remain attached to the mucosa causing ulcers, mainly in early summer. The localization of larvae in the buccal cavity of horses may lead to stomatitis with ulceration of the tongue, which may become infected with bacteria and cause microabscesses, impairing proper chewing. Similarly, larval attachment to the stomach provokes an inflammatory reaction resulting in chronic gastritis, loss of condition and even perforation and death.

The adult fly can cause irritation and intense avoidance reactions when hovering around the host and laying eggs on the skin. Larvae of *Gasterophilus* spp. may infest humans through direct oviposition on human body hair or upon direct contact with hatching eggs on a horse. External ocular myiasis by *Gasterophilus* spp. have been reported in humans. Removal of eggs from the host's coat is not practicable, but *Gasterophilus* spp. infestations can be easily controlled by broad-spectrum macrocyclic lactone compounds, such as ivermectin, by a single treatment during the winter.

Fig. 12 *Dermatitis hominis* third-stage larva typically pyriform with stout spines on the globular anterior portion. Photo: Lia RP.

Cuterebrinae

In the Cuterebrinae subfamily there are included six genera and 83 species, with *Dermatitis hominis* as the most known because of the wide range of infected animals, including humans from southern Mexico through Argentina. Other species belong to the genus *Cuterebra* that infest wild rodents and lagomorphs (and occasionally humans) in North America (Sancho, 1988). The life cycle of *D. hominis* is peculiar in that the female glues her eggs (800–1000) to the abdomen of a hematophagous insect, which approaches a potential host. The contact with the host and the increase in the temperature, elicits egg hatching and the penetration of the larva into the skin (Hall and Wall, 1994).

Larvae penetrate individually in the skin where they develop to L2 and L3 in four to 18 weeks, before dropping from the respiratory host into the environment and pupate. While the L1 is sub-cylindrical, the L2 and L3 (Fig. 12) are typically pyriform with stout spines on the globular anterior portion and no spines on the narrower posterior part and anterior spiracles. After emerging from the pupae, adults mate, living for 1–9 days without feeding (Sancho, 1988). *Dermatitis hominis* may cause severe cutaneous myiasis in cattle as well as in humans. Lesions caused by this myiasis are usually prone to secondary bacterial infection as well as larvae causing myiasis.

Medical and veterinary importance and control

Myiasis by *D. hominis* may be characterized by severe abscesses due to secondary bacterial infections, which may cause losses to livestock production due to reduced calf growth and weight gain, decrease in milk production, and hide damage. Also, sheep and dogs may be frequently attacked. Following the penetration of L1 (also through clothing), humans may present painful, discharging, cutaneous swellings on the body which heal soon after their removal. The only way to prevent the infection by *D. hominis* is the protection of bites by carrier insects (e.g. mosquitoes). Antibiotics should be prescribed if secondary infection is present or likely. Some proteins have been characterized for the development of potential vaccines against *D. hominis* for cattle (Fernandes et al., 2012), but so far no commercial vaccine has been licensed.

History and taxonomic positioning

There are several reports on the occurrence of myiasis in ancient times, e.g. “my flesh is clothed with maggots and encrusted with dust, my skin rotted and become loathsome” (Job 7:5); “the maggots will not turn into flies within you” (Papyrus Gizehn^c 18026:4 14) (Service, 1978). Infestation by maggots was considered a curse for bad men, like king Herodes (Book of Acts 12:23), also affected by high pressure, gangrene and renal insufficiency, Antioco IV Epifanius (Maccabees 2:9–12), Agrippa I and Judas Iscariotes (Montefiore, 2011). Aristotle, observing the appearance of maggots on skin, proposed the spontaneous generation theory.

Myiasis was part of a method of torture utilized by old Persians in scaphism, in which the victim was trapped between two boats, forced to eat milk and honey and exposed to flies, which produced serious anal lesions, and wasps (Lockwood, 2009).

Oestrus ovis (L.) already was referred in Biblical times as a dreaded pest of sheep, and the Greek physician Alexander Trallien referred to “sheep gad fly” in 560 CE.

Hernán Cortez, Conquistador of Mexico, branded his native prisoners on the cheek with a “G”, *Guerra* for war, sentencing many to death by infestation by screwworm attack. During second Opium War (1856–60), English prisoners died in prison after being tortured and attacked by maggots, provoking revenge by lord Elgin, which destroyed the beautiful Summer Palace, hurting Chinese people for a long time.

Myiasis (from ancient Greek *myia*, meaning fly) was proposed in 1840 by F.W. Hope for the infestation of tissues of living vertebrates by larvae of flies (Diptera), replacing scholichiasis, which referred to diseases caused by larvae of any insect.

Diptera is the fourth most diverse order of the Class Insecta, with approximately 150,000 species and 150 families described in two suborders: Nematocera and Brachycera (Brown, 2009). A little over 10% of dipteran families have at least one representative as obligatory or non-obligatory myiasis-causing. Once both types of parasitism, facultative or accidental, are nonspecific, it is impossible to quantify the exact number of species associated with this type of infestation worldwide, especially when parasitism occurs in the wild environment, where cases are rarely investigated.

In a recent review of reports of human myiasis, from 1997 to 2017, 464 cases were reported from 79 countries and caused by 41 species of flies (Bernhardt et al., 2018). A greater diversity on species in Asia, and a higher number of cases in the Americas and Caribbean were cited. Although the number of cases in Western Europe is very low, there could have been some lack of records, because the primary disease is the primary concern (Bernhardt et al., 2018) and there is some taboo (Hall et al., 2015).

The registry of parasitized vertebrates, both domestic and wild, is also numerous and includes amphibians, reptiles, birds, and mammals, including humans.

Biology of the myiasis-causing dipterans

The emergence of the habits causing myiasis and the transition to parasitism may have arisen from a broad adaptability process or by complete lack of specialization of a group to exploit the resources available in the nature (James, 1969).

According to Zumpt (1965), some species of flies that fed on corpses and feces began laying eggs on necrotic wounds or cavities of living animals due to the similarity of odors between such food resources—afterwards, some of these species have also developed the ability to invade living tissues, with the probable emergence of appropriate enzymes for this purpose. Thus, was drawn the first adaptive transition from saprophagy to parasitism.

Another proposed evolutionary route would be that larvae of some species, due to food scarcity, would have become facultative predators of other larvae. Subsequently, they were able to break the tegument of other larvae and suck their body fluids and, at a

later stage, started to pierce the skin of birds and mammals to suck blood. Finally, they would be able to go through the skin and lodge in the host's subcutaneous tissue, thus becoming an obligatory and hematophagous parasite (Zumpt, 1965).

From a parasitological point of view, i.e., taking into account the parasite-host relationship, myiasis can be classified as: (i) *obligatory*: refers to flies that feed exclusively on living tissues or other substances in the body of their hosts; in general, they exhibit parasitic specificity, since parasitism is the only resource that guarantees the perpetuation of the species involved (e.g., *Auchmeromyia* spp., *Chrysomya bezziana* (Villeneuve), *Cochliomyia homivorax* (Coquerel), *Cordylobia* spp. and *Lucilia* spp. (Calliphoridae); *Passeromyia* spp. and *Philornis* spp. (Muscidae); *Oestrus* spp., *Gasterophilus* spp., *Hypoderma* spp. and *Dermatobia hominis* Linnaeus Jr. (Oestridae); and *Wohlfahrtia* spp. and *Lepidodexia* spp. (Sarcophagidae)); (ii) *facultative*: when the larvae feed on the devitalized tissues (particularly the necrotic) of their hosts; in this case, their eating habit does not differ from that commonly observed in nature—where they are seen feeding on various sources of dead organic matter, therefore, it is a more opportunistic relationship than a parasite (among the most commonly involved fly families are Calliphoridae and Sarcophagidae); (iii) *accidental* or *pseudo-myiasis*: they can occur, but without any predictability, by unintentional ingestion of larvae or by the unusual penetration of larvae in the natural orifices of the host's body, causing disturbances of some gravity—among the most commonly involved fly families are Psychodidae (moth flies), Piophilidae (cheese skippers), Syrphidae (hover flies) and Phoridae (coffin flies).

Primary or *secondary* myiasis are also terms often used to define clinical conditions in which infestation begins without or with a pre-existing lesion, respectively. In addition, there are reports that take into account only the location where the larvae were found in the host, such as ocular, nasopharyngeal, anal, urogenital, enteric, cavitory, traumatic, furuncular, hematophagous, among others (Scholl et al., 2019).

Diptera are holometabolous, so their development, which undergoes a complete metamorphosis, includes four stages of life: egg, larva, pupa and adult. In general, myiasis-causing females lay eggs grouped in masses (Fig. 1A) (except *Oestrus ovis* and *Sarcophagidae* species that deposits larvae) on the edge of an open wound (Fig. 1B) (of whatever nature, e.g., umbilicus of young animals), in natural body openings or on/at the base of the hair (Fig. 1C) (in the last case, only *Hypoderma* spp.). It is not a rule, but infestations in natural openings are more frequent when there are injuries, poor hygiene, or in association with bacterial infections.

The larvae hatch within approximately 12–24 h and begin to feed on dead or living tissue (depending on the species of fly), reaching maturity within approximately 5–10 days (except oestrid flies, which can take 50–60 days to develop; Catts, 1982). Mature larvae leave the wound/body and burrow into loose soil to pupate. Adults emerge in 8–20 days and live on average 1–6 weeks, depending on the temperature and humidity. Females obtain protein to support egg production from wounds, excrement, or decaying animal matter, except oestrid flies that do not feed because their mouthparts are greatly reduced. Almost all females are attracted to the smell of the hosts' wound.

Although the biological cycle of myiasis-causing flies is similar, the behavior of some species to achieve a very successful parasitism can be quite peculiar. For example, *Cordylobia anthropophaga* (Blanchard) and *Auchmeromyia senegalensis* Macquart are found only in the Afrotropical region and the females of both genera laying the eggs on the soil, i.e., out of contact with the host (Zumpt, 1965). Newly hatched *Cordylobia* larvae seek a host and penetrate into their skin, causing a large abscess (= furuncle), while *Auchmeromyia* larvae remain free-living and repetitively seek blood from hosts, especially at night, causing only irritation. Females of bird parasites belongs to *Passeromyia* and *Philornis* genera lay eggs in nests and the newly hatched larvae, depending on the species, migrate to their hosts causing (furuncular) myiasis or only occasionally move to feed on blood.

Larvae of some species can also temporarily migrate to their hosts' cavities, or remain there until they reach larval maturity, causing so-called cavitory myiasis. Apparently, this behavior may increase the chance of offspring survival. Larvae of *Hypoderma bovis* (L.) and *H. lineatum* (Viller) (warble flies) migrate via the spinal column or oesophagus to skin, subsequently causing an abscess (Hall and Wall, 1995). When fully grown, larvae burrow out of the skin and drop into the ground to pupariate.

The route of *Oestrus ovis* (nasal bot flies) larvae in their host's body is not very long. Most of the time, the larvae can remain within the nasal sinus (place close to where the females originally deposit the larvae), and sometimes in the throat tissues (Fig. 1D and E). When the larvae are fully developed, they move down the nasal passage and drop into the soil to pupate. Parasitic species of *Lepidodexia*, which only parasitize anurans (Fig. 2A), have a behavior very similar to that observed for *O. ovis*.

The infestation by *Gasterophilus nasalis* (L.) or *G. intestinalis* de Geer (bot flies) starts in the mouth when the host (Li et al., 2019) licks the eggs that were deposited onto hairs by females, which are known for their persistence in flight around the hosts, causing a fear response. Larvae migrate to the stomach where they attach to the inner lining, but their bodies remain exposed to the stomach cavity. Their larvae are well adapted to such oxygen-poor environment. When ready to pupariate they release their hold on the wall of the gut, and are passed during defecation. Puparia are sometimes found in the dung.

Dermatobia hominis has a particular behavior related to the search for their hosts: females lay eggs on other insects, where they remain firmly fixed such that the insect-carrier (called phoretic) will carry them (Fig. 1F). To date, this dispersion strategy has not been observed among other myiasis-causing flies. *Musca domestica* L., *Stomoxys calcitrans* L., fanids and mosquitoes, probably due to the abundance and frequency with which they are observed living near humans and domestic animals, are among the most common *D. hominis* egg carriers (Guimarães and Papavero, 1999; Maia et al., 2018). Larvae hatch immediately in response to heat stimulation, CO₂ and probably vibratory movements of the host, after which they penetrate the subcutaneous tissue, individually, remaining at the same site until development is complete. This infestation is also referred as furuncular myiasis (Fig. 2B).

Regarding parasitic specificity, undoubtedly, oestrids (except *D. hominis*) and some species belonging to the genera *Philornis*, *Passeromyia* (Muscidae) and *Lepidodexia* (Sarcophagidae) exhibit the highest host-parasite specificity, in contrast to the low specificity observed in other families of myiasis-causing flies such as Calliphoridae and Sarcophagidae (Hall and Wall, 1995).

Fig. 1 Behavior and strategies of myiasis-causing flies to reach their hosts. (A) Blowflies females usually lay eggs, approximately 1 mm long each, grouped in masses to increase the offspring's chance of survival; (B) an example of an open wound on a cow's mammary gland: blood and injured tissue can attract flies to oviposition; (C) eggs laid at the base of the ox hair by *Hypoderma lineatum*; (D) and (E) *Oestrus ovis* larvae remain protected within the nasal sinus and sometimes in the tissues of their hosts' throat as they develop; (F) *Dermatitis hominis* eggs on *Fannia punctipennis*: the phoresy favors the wide dispersion of the "berne" fly. (B) Courtesy of Gustavo A. Faria, UNICAMP, Brazil; (C) Courtesy of Dr. Lyle J. Buss, University of Florida, USA; (D) and (E) Courtesy of Prof. Bruna F. Silva PhD, UNIPLAC, Brazil.

For example, the obligatory parasite *Wohlfahrtia magnifica* (Schiner) may deposit larvae on several healthy hosts without any predisposing conditions (Carnevali et al., 2019).

Global warming certainly is influencing distribution of myiasis-causing flies and intensity of attacks. Not only will the rise or temperatures, but also the shortening and softening of winters in the temperate regions increase the myiasis problem (Pitts and Wall, 2005).

Fig. 2 Main clinical pictures and pathologies observed in the myiasis by different species. (A) furuncular or cutaneous myiasis in *Rhinella jimi* (cane toad) (Anura) by a species of *Lepidodexia* sp. (Sarcophagidae); (B) and (C) furuncular myiasis by *Dermatobia hominis* leading to perforations in the cattle leather; (D) and (E) traumatic myiasis in livestock by *Cochliomyia hominivorax*—note extensive damage to the calf's ear in (C); (F) *Oestrus ovis* causing severe rhinitis and sinusitis in goat; (G) furuncular lesion with little severity in human head by *Cordylobia anthropophaga*. Pathology, distribution and economic importance

There are three basic forms of infestation that may also indicate, in part, the pathological processes resulting from parasitism on their hosts: (i) traumatic (sometimes called wound myiasis); (ii) furuncular; and (iii) cavitory.

Traumatic myiasis (Fig. 2D) is very serious, and it is usual, in large infestations, to cause the death of the hosts. Although the larvae remain most of the time only in the host's skin or integument (there are those that can occupy the natural cavities of the body, but still do not go very deep), they can cause extensive damage (= trauma) due to the voracity of most species associated with this type of myiasis ("eating machines"). In this way, it is important to highlight the difference between species that cause obligatory myiasis, which feed on living tissues, and species that cause facultative myiasis, which rarely cross the borders of colonized wounds,

since they stop eating when the devitalized tissue, its only food source, ceases. Among the main species that cause traumatic myiasis are: *Chrysomya bezziana*, *Cochliomyia hominivorax*, *Lucilia cuprina* (Wiedemann), *Lucilia sericata* (Meigen) and *Wohlfahrtia magnifica*.

Chrysomya bezziana, also referred as the Old World screwworm, is widely distributed in tropical regions of the Old World, particularly in the Oriental region. It parasites a wide range of mammals; in Africa, it attacks lions, impalas, rhinos and elephants, including humans and livestock (cattle, sheep, dogs, and pigs) (Zumpt, 1965). Other species of *Chrysomya* found around the world rarely cause myiasis; when this occurs, they are restricted to facultative parasitism.

Cochliomyia hominivorax, also referred as the New World screwworm, is confined to the Nearctic and Neotropical regions. This species parasites mainly the livestock (Fig. 2E) that live close to forested areas, causing economic losses that exceed US\$ 300 million/year (Grisi et al., 2014). Neonatal calves and post-parturient cows are especially susceptible to infestation.

Before European invasion of the American continent, introducing cattle, other mammals were attacked and continued to be hosts of this fly. Killing of 80% of white-tailed deers (*Odocoileus virginianus texanus*) was reported, in bad years, in the United States, and opossums and jackrabbits used also to be affected in that country, before its eradication (see Spradberry, 1994 for a review).

Unlike other flies that lay, on average, 50 eggs at a time, adult females of *C. hominivorax* can initially lay more than 100 eggs. The odor of a wound associated with that of a primary infestation can attract more females, both from *C. hominivorax* and other species of opportunistic flies, increasing the severity of the initial condition. For example, an infestation of 3000 larvae at once can cause the host to die within a few days.

Some diseases or comorbidities can also promote circumstances that will stimulate the attractiveness of females of *C. hominivorax* for oviposition. Thyssen et al. (2012) reported a case of high infestation in an elderly patient with periodontitis and a vulnerable state of health, which culminated in the loss of part of the palate and all teeth in the upper arch. Myiasis by *C. hominivorax*, in this particular case, was used as evidence of maltreatment, given that the patient was dependent on constant care.

In addition, many cases of human infestation have been reported. *Cochliomyia hominivorax* can cause extensive lesions on several regions of the body, including the face. Jean Charles Coquerel, which described this fly in 1858, had already noticed these facial lesions in Devil Island's prisoners. Oral and maxillofacial infestations, though less frequent than in other localizations, are frequently associated to teeth extraction, mouth breathing, *cancrum oris*, among others, developing to frightening situations (e.g., Antunes et al., 2011).

The genus *Lucilia* contains a large number of species distributed worldwide (Whitworth, 2014). Most species are saprophagous and for this reason are mainly involved with cases of facultative myiasis. Both *L. sericata* and *L. cuprina* play an important role in the obligatory parasitism of woolly animal breeds. Their larvae can quickly cause extensive lesions under the skin and inflammatory processes that cause a lot of irritation; in severe or untreated cases, it can lead the host to death. *Lucilia sericata*, known as a sheep strike, causes serious economic problems for sheep farmers in Africa, Australia, Northern Europe and New Zealand (Snoep et al., 2002). It is estimated that several million dollars are spent annually in loss of animals and attempt to control flies. Since the 1930s, *Lucilia cuprina* has been the most dominant causative agent of myiasis in Australia, and also causes economic loss of some significance in New Zealand (Heath and Bishop, 2006; James, 2006).

Why is *L. cuprina* not a problem for animal health in other parts of the world? To elucidate this question, Stevens and Wall (1996) studied the genetics basis of *L. cuprina* collected in Africa, Europe, Australasia, North America and the islands of Hawaii. The results supported the existence of an intra-specific genetic variation in *L. cuprina*, possibly related to geographical isolation (Stevens and Wall, 1997b) and strong climatic influence determining which species would become predominant in different geographic regions (Stevens and Wall, 1997b). Thus, in an independent evolution of the parasitic habit (Stevens and Wall, 1997a), *L. cuprina cuprina*, distributed in Neotropical, Oriental and Southern Nearctic regions, would be responsible for facultative myiasis, while *L. cuprina dorsalis*, found in Australasian, East and Sub-Saharan Afro tropical regions, a causative agent of obligatory myiasis.

Wohlfahrtia species infest many species of livestock (e.g., cattle, horses, sheep, goat, pigs) and other animals (e.g., donkeys, camels, dogs, cats, rodents and birds). Human infestations, particularly in the nose or eyes, are relatively rare. Both *Wohlfahrtia magnifica* and *W. nuba* Wiedemann, distributed in the Palearctic and Oriental regions, are responsible for traumatic myiasis, but *W. magnifica* is one of the most important obligatory parasites (Farkas et al., 2009), since *W. nuba* is associated with facultative myiasis.

The recent surging of infestation by *W. magnifica* in sheep in central Italy is possibly associated to introduction of Merino sheep, more susceptible to infestation (Giangaspero et al., 2011). Larvae of this species can cause severe damage to hosts, if not properly treated, since they grow quickly and are quite voracious (Carnevali et al., 2019). Consequently, large economic losses may be unavoidable.

In furuncular and cavitary myiasis, the larvae are not seen outside the body of their hosts. In the first case, the larvae penetrate the healthy skin and a furuncle develops, while in the second case, the larvae reach the internal cavities of the host's body, mainly the digestive and urinary tracts. Unlike traumatic myiasis, the larvae migrate very little (through the cavities) or nothing (when they form the furuncles) and feed basically on body fluids, but not on tissues. Thus, the damage caused by parasitism is strongly associated with the number of infestations per host. There are exceptions, but in general, parasitized individuals do not die. Among the main species that cause furuncular and cavitary myiasis are: *Dermatobia hominis*, *Gasterophilus nasalis*, *G. intestinalis*, *Hypoderma bovis*, *H. lineatum*, *Oestrus ovis* and *Cordylobia anthropophaga*. All species listed here are obligatory parasites.

Dermatobia hominis, which can also be called human botfly, berne (in Brazil) or tórsalo (in Spanish), occurs in the Neotropical region. This species parasites mainly cattle, but also several other mammals, including humans. For example, large infestations cause multiple skin lesions (boils) in cattle, whose devaluation of the leather can cause serious financial losses, estimated at ca. U\$

280 million/year in Brazil (Grisi et al., 2014). Exportation of leather produces revenues of 2.48 billion dollars to Brazil, but 40–89% of it have perforations (Fig. 2C) caused by this fly (Gomes, 2002).

Gasterophilus nasalis and *G. intestinalis* can be found worldwide and live exclusively in the alimentary canal of horses. Infestations rarely cause problems. Both species in heavy infestations can cause gastric ulceration, peritonitis, gastroesophageal reflux, splenitis and pleuritis (Uzal and Diab, 2015).

Hypoderma bovis and *H. lineatum* infest cattle in the Palearctic, Nearctic and Neotropical regions; and sometimes horses or sheep, but the life cycle is not completed in the latter. Both *Hypoderma* species can cause a great amount of damage to the health of the cattle and to their hides, similar to what is observed for *D. hominis*, though these flies have been eradicated in many countries in Europe.

Oestrus ovis parasites sheep and goats worldwide, causing rhinitis and sinusitis, sometimes severe (Fig. 2F); encephalomyelitis was observed in a goat. This parasite fly rarely is found in humans. In rural areas, females can deposit larvae in the conjunctival sac of humans, particularly those who live in close contact with sheep (Angulo-Valadez et al., 2010). Infestation has also been reported in llamas and alpacas, the South American camelids (Angulo-Valadez et al., 2010).

Cordylobia anthropophaga infests humans (Fig. 2G), dogs, cats and some wild mammals. This fly is found in the Afrotropical region, though an autochthonous human case was reported in Portugal (Curtis et al., 2015). The pathology of *C. anthropophaga* infestations is generally less severe than those caused by *D. hominis*, with some swelling and infection (Hall and Wall, 1995). Zumpt (1965) reported that adult females can lay eggs on clothes hanging to dry, which explains infestations in which an individual does not observe flies flying around them.

There are other intriguing species of myiasis-causing flies and unfortunately little studied such as those of the genera *Passeromyia* (Palearctic and mostly in the Old World) and *Philornis* (in the New World), parasites of wild and captive birds; and *Lepidodexia* spp. (in Neotropical region) and *Lucilia bufonivora* (in North West Europe and Canada), both parasitizing anuran and sometimes causing relatively high mortality rates among some hosts (Weddelling and Kordges, 2008; Grzywacz et al., 2014; Arias-Robledo et al., 2018; Mello-Patiu, 2019). For example, *Philornis downsi* Dodge & Aitken, recently introduced to Galápagos Islands, has drawn worldwide attention for being responsible for the deaths of almost 100% of Darwin's finch chicks in recent years (McNew and Clayton, 2018).

Several abiotic and biotic factors can affect how a given animal species is distributed, but in the particular case of myiasis-causing flies it is important to be aware of the fact that some species can be transported from place to place together with their hosts, or accidentally, by plane and boats. For example, three *Chrysomya* species—*C. albiceps* (Wiedemann), *C. megacephala* (Fabricius) and *C. putoria* (Wiedemann)—became widely distributed in the American continent after the independence of Angola and Mozambique, with massive migration of Portuguese people, and their domestic animals, to this continent (Guimarães et al., 1978, 1979; Baumgartner and Greenberg, 1984; Wells, 1991). In the 1980s, a dog infested by *C. hominivorax* was found in France (Chermette, 1989); this same species was introduced and spread over almost 25,000 km² in Libya (Lindquist et al., 1992). The invasion of Libya by *C. hominivorax* could have been catastrophic, if it had followed Nile valley to sub-Saharan Africa (Woodford, 1992). According to an analysis by CLIMEX, potential distribution of *C. bezziana* in the American continent would be the same of *C. hominivorax*, and it could invade even the southern regions of Australia, like New South Wales (Sutherst et al., 1989).

Diagnosis

Before removing the larvae, it is recommended to identify and record the type of pathology associated with the myiasis in question, whether traumatic or furuncular. After proper cleaning of the lesions, collect the larvae, if necessary using tweezers and transfer them to a vial containing 70° GL ethanol or formalin. Although information on patients' previous travels can be useful in identifying unusual myiasis, the larvae must be sent to specialists for identification.

In general, the larvae can be identified mainly through characteristics such as body shape, size, presence and pattern of distribution of spines in the integument and conformation of respiratory stigmas (Fig. 3; Marcondes and Thyssen, 2017). Publications such as those by Zumpt (1965), Guimarães and Papavero (1999) and Szpila et al. (2014, 2015) can be very useful for identification, since they bring keys and/or illustrations of anatomical structures with diagnostic value.

For the identification of cavity myiasis, like those of *Hypoderma* spp. and *Oestrus ovis*, serological and molecular methods have been successfully utilized (Otranto et al., 2004), including ELISA for *Gasterophilus* spp. (Migueléiz et al., 2016). A molecular test developed for larvae of *Rhinoestrus* spp. infesting nasal cavities, synuses and pharynx of equids was also proposed for other myiasis-causing flies (Traversa and Otranto, 2006). Molecular differentiation has been utilized for *Hypoderma* spp. from Turkey and Pakistan (Ahmed et al., 2017).

PCR in nasal mucus produced respectively 100% of sensitivity and specificity for goats, while rhinoscopy produced 100% of sensitivity and specificity for goats, but 100% of specificity and only 81% of sensitivity for sheep for *O. ovis* infestation (Ipek and Altan, 2017). This molecular technique permits sure diagnosis without killing the host.

Recently, *D. hominis* had its Cytochrome Oxidase and ITS-2 genes characterized (Martínez-Hernández et al., 2019; Touissant-Caire et al., 2018) for diagnostic purposes. In addition, Touissant-Caire et al. (2018) found a 98% similarity between individuals from Mexico and other locations in South America. Larvae of this species can be easily identified through traditional morphological examination, but when it comes to a case involving the encounter of a non-endemic species of a region it is advisable to conduct studies such as these integrating morphological and molecular data to avoid misidentification. Grella et al. (2015) using the integrated taxonomy demonstrated that a non-endemic species of *Chrysomya* had been mistakenly registered for Brazil.

Fig. 3 Larvae of several myiasis-causing flies. From A to N, U, Y and Z, lateral or dorsal view. From O to T and from V to X, posterior view, showing respiratory spiracles with diagnostic value. In: (A) and (O) *Cuterebra* sp.; (B) *Hypoderma bovis*; (C) and (P) *Hypoderma lineatum*; (D) and (Q) *Oestrus ovis*; (E) and (R) *Gasterophilus intestinalis*; (F) *Gasterophilus nasalis*; (G) and (S) *Dermatobia hominis*; (H) and (T) *Sarcophaga* sp. (Sarcophagidae); (I) and (U) *Cochliomyia hominivorax*, showing the pigmented tracheas; (J) *Chrysomya megacephala*; (K) and (V) *Chrysomya albiceps*; (L) and (W) *Lucilia eximia*; (M) and (X) muscid fly; (N) *Fannia* sp.; (Y) *Auchmeromyia* sp.; (Z) *Cordylobia anthropophaga*. Cham: Springer, reused with permission from Springer, 2020 (Richard Lansing). *Hypoderma* figures—http://entnemdept.ufl.edu/creatures/livestock/cattle_grub.htm.

Bernhardt et al. (2018) pointed out several problems with misidentification of myiasis-causing species and with the increase in the number of cases associated with humans in Europe. They also stressed how important the correct identification is to improve the monitoring and treatment of parasitized individuals.

The chance of misidentification of a species that is parasitizing a traveler is relatively high, when disregarding information about the regions visited. Probably, this is the case of infestation by *D. hominis* in a traveler recently visiting Africa and of a report of autochthonous cases from Saudi Arabia, in whose southwestern region *C. anthropophaga* had already been reported, and a case of infestation by *C. hominivorax* in the North of India. However, this does not mean the distribution of myiasis-causing flies cannot change, as observed by an above cited report of autochthonous infestation by *C. anthropophaga* in Portugal, diagnosed on the return of the patient to United Kingdom, and practically excluding contamination by clothes (Curtis et al., 2015).

Although furuncular myiasis is usually caused in Africa by *C. anthropophaga*, a human case of infestation by *Cordylobia rodhaini* Gedoelst (Lund's fly) in a man returning to Italy from Uganda was reported, and a review of 25 cases reported since 1902 was provided (Pezzi et al., 2015). This species usually parasitizes monkeys, rodents and small antelopes, emphasizing the need of accurate identification. Another issue to be considered is that many infestations may have been unreported.

Treatment and prevention

If a traumatic myiasis in humans is in place, all larvae must be removed from the wound or orifices, which need to be cleaned and disinfected afterwards. Careful treatment and protection of wounds in the skin or mucosal orifices are essential to prevent infestation. Rooms of clinics and hospitals where wounded or recovering after surgical procedure patients are maintained need to be protected by nets on windows and doors, or bed nets need to be utilized.

In domestic animals, some drugs have been utilized, mainly ivermectin and other avermectins, for treatment or prevention against several myiasis-causing flies. For example, 110 artificially wounded steers, castrated bull calves and newborn calves were divided in two groups: 55 of them treated by 200 µg/kg of ivermectin were totally protected from infestation by *C. hominivorax*, while from 25% to 53% of 55 control animals in similar conditions animals became infested (Anziani and Loreficce, 1993). However, a potential resistance of *D. hominis* to ivermectin and moxidectin in the usual dose (200 µg/kg) was reported in cattle, with some larvae surviving to treatment (Neves et al., 2015).

Control of myiasis in animals have also been done through the use of chemical compounds, mainly organophosphorus insecticides, macrocyclic lactones and, more recently, a foamy spray based on spinosad. For example, dicyclanil is used as insect growth regulator on castration wounds in cattle and has been quite effective in preventing infestations by *C. bezziana*.

In Italy, the efficacy of a plant-derived formulation, composed of neem oil (*Azadirachta indica* A. Juss.) and the oily extract of *Hypericum perforatum* (L.) flowers, has been investigated against *W. magnifica* with successful results. Forty-four infested domestic animals, among which sheep, bovine, goat, swine, equine, canine and rabbit, were treated and all wounds healed between 10 and 32 days, without further infestation (Camevali et al., 2019). Other researches have been conducted to test the use of essential oils and natural plant extracts to kill larvae of *Lucilia* spp. (Khater et al., 2011).

For the treatment of furuncular myiasis (e.g., by *D. hominis* or *C. anthropophaga*), one proposed method is asphyxiation of the larva for subsequent removal of the insect with the aid of a tweezer. To remove larvae of *O. ovis*, cavities in the head of host need to be washed, but this may not always be effective.

Caution is recommended when drying clothes in the environment for avoidance of *C. anthropophaga*; and it is also recommended that people sleep on beds (or hammocks) to reduce parasitism by *Auchmeromyia* sp.

Control

Inspection and treatment of all infested animals are too time-consuming. In addition, insecticides and traps have not been effective for the control of several parasite species due to short time of residence on the host and short generation time. *Cochliomyia hominivorax* was the first insect to be controlled and eradicated using sterile insect release, in a program known as Sterile Insect Technique (S.I.T.), proposed by Knipling (1955). This technique consists of releasing sterilized males on the field in numbers sufficient to overwhelm the wild population, with the idea that sterilized individuals will compete with wild normal males. Successful results have been obtained in the United States and in several Caribbean islands (Spradberry, 1994; Guimarães and Papavero, 1999). However, dogs, pigs and deers have recently been found in Florida (mainland and Florida Keys) (Hennessey et al., 2019).

Studies are currently underway to develop a synthetic odor bait to attract female *C. hominivorax*. It could be used to monitor *C. hominivorax*, besides helping to reduce the population in infested regions (Cork and Hall, 2007). For the control of *L. cuprina* and *L. sericata*, the removal of skin from the breech in certain breeds of sheep and tail-docking are the most effective non-chemical method for control, by preventing favorable ovipositing sites. However, genetic methods, by selection of breeding more resistant to sheep strike and adequate techniques of mulesing and tail-cutting, have been proposed to replace such time-consuming methods (James, 2006). Treatment of sheep for helminthic infection, to prevent diarrhea, also is important.

In England, tests conducted on sheep farms have demonstrated the effectiveness of using traps for catching adults of *L. sericata* for reducing flies in the environment, and consequently reducing the number of attacks on animals (Broughan and Wall, 2006). The

same study showed that there was no significant difference between using traps as a single strategy and using traps combined with chemical treatment of animals. This finding appears to be a promising strategy for reducing insect populations without promoting selection of resistance to the insecticide in the medium and long term.

Due to the complexity of the *D. hominis* life cycle, efficient strategies for its control are not available. Guimarães and Papavero (1999) pointed out that open formations seem to be a barrier to the dispersion of *D. hominis*, since this species is more abundantly found on the margins of primitive or secondary forests, gallery forests or eucalyptus plantations.

Vaccination of livestock has been explored both in vitro and in vivo against some species of myiasis-causing flies, but this issue is still unresolved.

Additional aspects of myiasis-causing flies

Some myths have been associated to myiasis. Carcasses of *Cuterebra*-infested squirrels and rabbits are usually discarded in United States, supposing these animals are unfit to eat, but in the Arctic and sub-Arctic cultures not only the meat of reindeer or caribou infested by *Hypoderma tarandi* is regularly eaten, and these larvae (located on animal's back) are considered a delicacy by the natives (Scholl et al., 2019). *Cephenemyia* adults were considered to fly at very high speed, supposedly to attack deer, but there are no indications of speeds higher than 28 km/h, and they attack their hosts when they are still (Scholl et al., 2019). Larvae of *Cuterebra emasculator* were supposed to consume the testis and emasculate their squirrel and chipmunk hosts, but they only prevent the seasonal descent of gonads into the scrotum, due to the presence in the scrotal sack.

The horror of harboring or viewing maggots can cause reactions severe enough to result in mental disorders and self-mutilation (Clarke, 2013). Delusional parasitosis (Ekbom syndrome) includes the so-called “matchbox sign,” in which the patient present supposed parasites, frequently incriminating maggots. However, some patients may be correct on the allegations, as an Indian patient, which had many larvae of *Musca domestica* in his large gut.

Adapted to feed and survive in contaminated environments, maggots have the capacity to kill many types of bacteria. Observation of cleaning and improvement of wounds of several origins through infestation by larvae of secondary myiasis-causers stimulated the development of laboratory colonies, and sterile larvae have been purposely applied on wounds. Mostly *Lucilia* spp., and recently *Chrysomya megacephala* (Pinheiro et al., 2015) and *Cochliomyia macellaria* (Nassu and Thyssen, 2015; Masiero et al., 2019) have been utilized, but several other species have been tested for this very efficient maggot debridement therapy (MDT). This therapy, used to heal wounds quickly with minimal scarring, has been utilized in several countries, mostly in Europe, Israel and United States, but also in Brazil, Colombia, Chile, Egypt, Australia etc. (see: www.BTERFoundation.org) (Fleischmann et al., 2004; Marcondes, 2006).

Determination of time and conditions since death is very important, mostly in cases of suspect of crime. Since this determination is difficult, infestation of corpses by insects, in particular by dipterans, can provide useful information (Thyssen et al., 2018), as part of forensic entomology.

From Spradberry (1994):

It is doubtful that the mind of man could create a more vile (sic) scene than that of worms consuming the live flesh of one's body. The imagination almost refuses—particularly in this day and age—to conjure up the horrendous pain and outright revulsion that must come to a person infested with a writhing, seething mass of worms steadily tearing and consuming his flesh.

From C. E. Scruggs (1975).

Introduction

The order Diptera, more than the other orders, has many families characterized by an evolutionary adaptation in the trophic behaviour: the hematophagy (Petersen et al., 2007). Representatives of these groups have modified the mouthparts in piercing-sucking appendages to feed on the blood of many vertebrate species. Thus, the mouth apparatus has evolved in different types influenced by the feeding behavioural mechanisms: species that insert their thin appendages into the skin of the host reaching the capillary net, injecting saliva and taping the blood, termed solenophages, or species that by the external teeth-like structures scratch the host skin and feed on the spilled blood termed pool feeders (Afonso et al., 2012; Mehlhorn, 2018).

Mosquitoes, which belong to the suborder Nematocera, are important vectors that carry the most severe diseases plaguing humans. A major example is represented by malaria, caused by *Plasmodium* parasites vectored by *Anopheles* spp. (Benelli and Beier, 2017), a plague yearly affecting more than 2 million of people and has produced 405,000 deaths worldwide in 2018 (WHO, 2019) of note, *Aedes* and *Culex* vectors are crucial in spreading arboviruses. For example, *Aedes aegypti* and *Aedes albopictus* act as vectors of dengue, chikungunya, and Zika in humans (Powell, 2018; Benelli et al., 2020).

In the suborder Brachycera there are important flies acting as mechanical transmitters of pathogens (e.g., bacteria) and parasites (e.g., protozoan cysts and helminth eggs), and some species play an important role also as intermediate host or biological transmitters. Furthermore, some are blood-sucking and attack both humans and animals (Iwasa, 1983; Onmaz et al., 2013). Acalyptrate flies of the family Psychodidae, Simuliidae Ceratopogonidae are important vectors of diseases such as haemosporidian parasites or bacteria of genus *Bartonella* as well as filarial nematodes (Durden and Mullen, 2019; Santiago-Alarcon et al., 2012; Afonso et al., 2012). In high Calyptrate Diptera, the family Muscidae has some important hematophagous species such as *Stomoxys calcitrans*, a worldwide distributed fly responsible of considerable economic losses in dairy farms. Flies generate direct nuisance such annoyance and blood loss in cattle, and some representatives are implicated as mechanical vectors of important viruses like West Nile Fever Virus (WNV) or the African Swine Fever Virus (ASFV) (Baldacchino et al., 2013). In the superfamily Hippoboscoidea, the family Glossinidae includes representatives responsible for the transmission of some *Trypanosoma* spp. that cause the Human African trypanosomiasis or the African animal trypanosomiasis, which cause the “sleeping disease” and the “nagana” respectively in humans and in livestock (Vreysen et al., 2013). Finally, Hippoboscidae (ked and louse flies), Streblidae and Nycteribiidae (bat flies)

are implicated in the horizontal and vertical transmission of protozoa, bacteria as well viruses and nematodes to wildlife, and often responsible of direct damage to humans causing allergic reactions by their bite (Reeves and Lloyd, 2019). The present chapter reviews current knowledge about these interesting families, describing the biology, ecology, morphology and behaviour of some species which are important from veterinary and medical point of view, and providing insights on current control tools available in the Integrated Pest/Vector Management scenario.

The superfamily Hippoboscoidea

Hippoboscoidea is a superfamily of hematophagous ectoparasites belonging to the order Diptera and includes four recognized family level-taxa: Glossinidae, Hippoboscidae, Nycteribiidae and Streblidae. All of these families were grouped under the name Puppipara because they are viviparous and deposit larvae that quickly pupate. Currently, the name Puppipara is recognized as being improper because females lay fully developed larvae instead of pupae. For this reason, it is incorrect to consider this superfamily as pupiparous but larviparous (Reeves and Lloyd, 2019).

Hippoboscidae commonly are referred to as keds or deer keds, or as feather, bird, or louse flies, while Nycteribiidae and Streblidae are known as bat, flat or spider flies (Reeves and Lloyd, 2019). The family Hippoboscidae includes several parasites of mammals and birds, while the other two families are exclusively limited to bats (Hutson, 1984).

Members of Hippoboscoidea are characterized by several peculiar morphological and biological traits. Their reproductive strategy is adenotrophic viviparity: larvae are contained singly in the mother's uterus and are nourished from structures named "milk-glands," well-described by Benoit, et al., 2015. When a third-instar larva is fully developed, it is deposited by the female and shortly thereafter pupates. Females larviposit in different substrates depending on the species. Some flies deposit larvae in nests, others on the host animal fur, but some attack larvae to roost walls or glue them to the host wool. Fully-grown larva is legless with a barrel-like soft body (Maa and Peterson, 1987), while the puparium is similar to the mature larva with more sclerotized cuticle (Fig. 1). In many hippoboscids, the emergence of a new generation occurs simultaneously in a determined range with the year, with pupae able to overwinter in diapause, depending on the larviposition period (Bequaert, 1953; Hutson, 1984).

Fig. 1 *Lipoptena cervi*. Gravid female (artificially depigmented) showing a mature larva inside the uterus (A); female larvipositing (B); barrel-like larva just out of the mother's body (C); typical dark sclerotized puparium (D).

In the adult stages, all members of Hippoboscoidea are obligate and permanent blood-sucking ectoparasites, feeding on various host species. Generally, a fly is specialized in attacking a specific host or a few related groups, but occasionally can feed on other species, called “accidental hosts,” which are used as food source but on which reproduction does not occur (Maa and Peterson, 1987). Within the superfamily, species exhibit varying parasitism levels. Some species are monoxenous, meaning they are associated exclusively with a single species; others are stenoxenous, and can infest a phylogenetically related group, or oligoxenous if they parasite a limited number of hosts restricted by ecological factors only; others instead are polyxenous and are able to live on a wide range of species (Hutson, 1984; Lourenço and Palmeirim, 2008).

To live in close association with hosts, these ectoparasites have co-evolved with them adapting morphologically and physiologically (Guerin et al., 2000). For instance, parasites of birds synchronize their life cycle with host seasonality: adults die when birds migrate, and the emergence of a new generation coincides with host return (Bequaert, 1953). Similarly, aggregations of bat flies live in caves together with their gregarious hosts. When a bat exits the cave to search for food, female parasites leave the host to deposit pupae on the walls (Peterson and Wenzel, 1987). Finally, deer keds are strictly dependent on a single suitable host specimen and spend the entire life on the fur of the host (Bequaert, 1942).

Representatives of Hippoboscoidea are adapted morphologically for ectoparasitic life and display numerous structures that allow them to efficiently live together with their hosts (Petersen et al., 2007). Their body is dorsoventrally flattened with several reduced and fused regions and a sclerotized exoskeleton that is able to withstand mechanical stresses caused by host movements. Females show a strong reduction or disappearance of abdominal sternites with large intersegmental membranous areas allowing the develop of the larva in the mother's uterus (Fig. 2). Additionally, parasites have peculiar adhesion organs that permit the adherence to animals (Maa and Peterson, 1987; Petersen et al., 2018; Reeves and Lloyd, 2019). Among the three families, Nycteribiidae are modified morphologically to the extent that they no longer resemble most Diptera, while Streblidae are unusually variable in features and structures between their species (Hutson, 1984; Petersen et al., 2007). The head is prognathous in Hippoboscidae and Streblidae, while in Nycteribiidae it is protruding from the dorsal thoracic area (Maa and Peterson, 1987; Dick and Patterson, 2006). Both sexes of Hippoboscoidea are hematophagous and feed using highly adapted mouthparts consisting of a slender proboscis embraced in two concave, bristled, and sclerotized palpi. The alimentary canal is formed by the union of labrum, hypopharynx, and labium (theca sensu Snodgrass, 1943). Labella end the proboscis and bear at the tip different kinds of teeth and sensilla (Fig. 3) (Snodgrass, 1943; Peterson and Wenzel, 1987; Wenzel and Peterson, 1987; Andreani et al., 2019).

Some species are wingless in the adult stage, e.g., nycteribiids or some hippoboscids such the sheep ked, *Melophagus ovinus* (Linnaeus, 1758), while others are caducous-winged and shed wings once settled on a suitable host, as in the subfamily *Lipopteninae* of Hippoboscidae. Finally, others, instead, maintain either reduced or fully developed wings, like in Streblidae and some species of the Hippoboscidae family, such as *Hippobosca equina* (Linnaeus, 1758) or the louse fly *Pseudolynchia canariensis* (Macquart, 1840) (Hutson, 1984; Liu et al., 2019).

The lifecycles of some Hippoboscoidea have been drawn and presented below (Figs. 4–7).

The Family Hippoboscidae

Bio-taxonomy, morphological adaptations and behaviour

The family Hippoboscidae is composed by three subfamilies and includes a total of 213 described species divided in 21 genera (Dick, 2006). The subfamily Ornithomyiinae is the most numerous with 16 genera and 171 species; the subfamily Hippoboscinae, instead, consists of two genera with eight species, while three genera and 34 species form the Lipopteninae subfamily (Maa and Peterson, 1987; Dick, 2006).

Among the genera, host specificity is more marked in flies attacking mammals, while bird parasites live at the expense of a higher range of hosts (Reeves and Lloyd, 2019). Compared to the other two families belonging to the Hippoboscoidea, Hippoboscidae includes highly variable species in terms of morphology, biology, and behaviour.

The head of hippoboscids is prognathous with mouthparts consisting of two well-sclerotized palpi embracing the piercing apparatus, called also proboscis (haustellum sensu Snodgrass, 1943). It ends with two labella bearing a series of different types of sensilla and teeth-like structures which allow to scratch the skin of the host. The fly thus can feed on the blood spilled from the injury. Other interesting features strongly adapted in these flies are the legs. They are provided with an acropod (pretarsus) equipped with modified adhesion organs such as claws, pulvilli, and empodium. These structures are armed differently among species, but they allow the parasite to live together with the host during most of the life-cycle (Fig. 8).

Lipopteninae subfamily is known to infest ruminant Artiodactyl mammals, especially Cervidae and Bovidae (Bequaert, 1942; Hutson, 1984). This group is divided into three genera: *Lipoptena*, *Melophagus* and *Neolipoptena*. Except *Melophagus* genus, which is totally wingless, the others have caducous wings that show a predetermined horizontal breaking line. Flies lose these structures during the passage between the fur of the host (Haarlov, 1964). Lipopteninae species need a single suitable specimen to survive. Due to their loss of wings once on-host, it is difficult for these species to switch host. Pupae are laid on the hairs of the fur but fall to the ground as a result of the mammal movements; the emergence of a new generation occurs in a specific range of time. New adults are winged and search for a specific host, they are not able to move for long distances and remain near the emergence site (Bequaert, 1942).

Ornithomyiinae is the largest subfamily of Hippoboscidae. About 75% of hippoboscid species exclusively parasite birds and all of them belong to this subfamily (Hutson, 1984). Eighteen bird orders are infested by Hippoboscidae (Santos Murgas et al., 2014). The genera within this group are related more strictly than those of the other two subfamilies. Parasites live in close association with their victims and display different level of host specialization, some are limited to one or few species, while others affect a wider range of hosts. Pupae are deposited in bird nests and the life cycle is synchronized with those of the hosts (Bequaert, 1953). These species have peculiar morphological structures that assist them in remaining on the host during its flight.

Subfamily of Hippoboscinae is indigenous throughout the continental areas of the Old World. All species of this subfamily are ectoparasites of mammals, with the exception of *Struthibosca struthionis* (Janson, 1889) which solely parasite ostriches. Flies of this subfamily infest mainly ungulates and carnivores showing less host specificity compared to Lipopteninae subfamily. They are winged during all their adult life and are good fliers able to switch host frequently (Bequaert, 1930).

Species of Hippoboscidae family can establish phoretic associations with mites, fleas and lice (Maa, 1966; Maa and Peterson, 1987; Megat Abd Rani et al., 2011; Amaral et al., 2013). This aspect can be relevant for the public health, because of the possible transmission of zoonotic microorganisms carried by flies.

Several species of the three subfamilies have been confirmed as potential and/or vectors of various pathogenic agents from veterinary and medical point of view. Consequently, studies on the biology of these parasites are increasing thanks to the modern molecular technologies in order to understand their sanitary role as well as their economic importance.

Relevant Hippoboscidae species for animal and human health

Subfamily Lipopteninae

Lipoptena cervi (Linnaeus, 1758)

The fly is a Palearctic species, nowadays distributed worldwide (Fig. 9). Originally it has been recorded in Europe, Siberia and North China, but subsequently the species has spread into Asia, North Africa and North America, mainly as a result of both intentional and accidental introductions (Bequaert, 1942). Currently, this fly is the most widespread species in Europe (Salvetti et al., 2019). It is usually named “deer ked” as it infests several species of deer. In fact, many species belonging to the Cervidae family are suitable hosts for the parasite (Haarlov, 1964). In Europe, the fly predominantly parasites moose (*Alces alces*), red deer (*Cervus elaphus*) (Fig. 10), and to a lesser extent reindeer (*Rangifer tarandus fennicus*) roe deer (*Capreolus capreolus*) and fallow deer (*Dama dama*). Recently it adapted to few Bovidae species; in fact, some flies have been recorded on chamois (*Rupicapra rupicapra*) and mouflon (*Ovis musimon*) (Ferron, 2008; Bianchi et al., 2016). Moreover, it can occasionally parasite other species used as a food source, such as horses, cows, dogs, cats, badgers, boars, and humans (Bequaert, 1942; Hermosilla et al., 2006). *Lipoptena cervi* has become a pest for animals and humans. In the past this parasite has reached a very high density in Finland, causing such nuisance that people strongly reduced recreational and professional activities in woodland (Härkönen et al., 2009). The infestation can be surprisingly high, in fact up to 17,500 flies have been counted on a single moose, with severe consequences for the host, as skin injuries, dermatitis and alopecia (Kaunisto et al., 2008; Madslien et al., 2011). Parasitism affects also the behaviour of the hosts, increasing defensive or restless actions (scratching, grooming, shaking) with a decrease in the general animal welfare (Kynkäänniemi et al.,

Fig. 8 *Pseudolynchia canariensis*. Frontal view of the head and anterior legs (A); dorsal view of the prognathous head (B). *Hippobosca equina*. Mouthparts with sclerotized palps embracing the proboscis (C); detail of the proboscis tip bearing teeth-like structures and sensilla (D). *Lipoptena* spp. Acropod with asymmetric claws (E). *P. canariensis*. Acropod with three differently sized claws (F).

Fig. 9 *Lipoptena cervi* adults. Female (A) and male (B). Modified from: Andreani A, Sacchetti P, Belcari A (2019) Comparative morphology of the deer ked *Lipoptena fortisetosa* first recorded from Italy. *Medical and veterinary entomology* 33: 140-153.

Fig. 10 Red deer thigh and breast with a high infestation of *Lipoptena cervi* and *L. fortisetosa*. (A and B); detail of an adult of *Lipoptena cervi* moving through the guard hairs of the host (C).

2014). Besides mechanical harms, recent studies have identified *L. cervi* as potential vector for several pathogens. *Borrelia burgdorferi*, etiologic agent of Lyme disease, has been detected and identified in flies, as well as *Anaplasma phagocytophylum*, responsible for human and animal granulocytic anaplasmosis; in some case the specimens were infected with both pathogens (Buss et al., 2016). It is possible that the parasite is a mechanical vector for the transmission of these agents, acquiring them from the blood of an infected deer. This hypothesis is confirmed also by lack of these pathogens in the winged flies (Víchová et al., 2011). Moreover, *L. cervi* is considered a potential carrier for *Trypanosoma* spp. (Böse and Petersen, 1991) and *Bartonella* spp. (Dehio et al., 2004; Halos et al., 2004; Regier et al., 2018), responsible of human dermatitis. Presumably, *Bartonella schoenbuchensis* is vertically transmitted from the infected females to the new generations, in fact the pathogen has been detected in larvae and pupae, winged and wingless adults, and colonize the midgut of flies (Dehio et al., 2004; de Bruin et al., 2015). In Norway *L. cervi* seems to contribute to infect moose with *Bartonella* spp. (Duodu et al., 2013). In addition, *Acinetobacter baumannii* DNA has recently been detected in one specimen of *L. cervi*, proving that the parasite can contribute to the spread of this pathogen, affecting people with compromised immune systems, in human and animals (Regier et al., 2018). Although the presence of pathogen DNA in the flies does not imply their competence as biological vector, it suggests that *L. cervi* can increase the spread of the agent to humans and animals. However, the possible mechanical transmission of the pathogen entails the risk to infect other subjects via the bite of the parasite.

***Lipoptena depressa* (Say, 1823)**

Lipoptena depressa has been divided taxonomically in two different subspecies: *L. depressa depressa* (Say, 1823) and *L. depressa pacifica* (Maa, 1969; Dick, 2006). These two subspecies are differently distributed: the first occurs in several central states of the USA, while

the other occupies the eastern part of USA and Canada (Reeves and Lloyd, 2019). *Lipoptena depressa* attacks several subspecies of the ungulate *Odocoileus hemionus* (i.e., *O. h. hemionus*, *O. h. columbianus*, *O. h. californicus*, *O. h. fuliginatus*) (Bequaert, 1953). Moreover, it is a likely parasite of *Odocoileus virginianus leucurus*, the Western white-tailed deer, and has been found on other accidental hosts, such as horses and pigeons. Although in USA the infestation areas occupied by *Lipoptena* species seem to be divided geographically, in western North America *L. depressa* and *Neolipoptena ferrisi* frequently occur together on the same host, as well as *L. cervi* and *Lipoptena fortisetosa* in Italy (Andreani et al., 2019; Skvarla and Machtinger, 2019). *Lipoptena depressa* is considered a potential vector for *Anaplasma* (Skvarla and Machtinger, 2019).

***Lipoptena fortisetosa* Maa, 1965**

The species (Fig. 11) is native to Japan but currently has been identified in few other countries in Asia and Europe (Choi et al., 2013). Its original host is the Japanese deer, named Sika deer (*Cervus nippon*) (Maa, 1965, 1967), although it has been recorded also on the other hosts, such as deer, cattle, goat, sheep, dog, passerine birds and humans (Schumann and Messner, 1993; Yamauchi et al., 2009; Sokół and Gałęcki, 2017; Kurina et al., 2019). In all the countries in which *L. fortisetosa* has been recorded, its presence is considered to be related to the Sika deer, frequently introduced and considered one of the major naturalized alien ungulates in Europe (Mogi, 1975; Sonobe, 1979; Yamauchi and Nakayama, 2006; Choi et al., 2013; Raganella Pelliccioni et al., 2013). On the contrary, Kurina et al., 2019 report that just few Sika deer recently have been counted in Estonia, suggesting that this host cannot be the mean by which *L. fortisetosa* arrived in this area. However, it is undoubted that this hippoboscid is continuously expanding its range, in fact in the last years several occurrences have been recorded in further European countries (Sokół and Gałęcki, 2017; Andreani et al., 2019; Kurina et al., 2019; Mihalca et al., 2019). *Lipoptena fortisetosa* is poorly investigated for possible implications to animal and human health, but, as other hippoboscid species, mechanical damages on the host skin have been attributed to this species, as well as anaemia and hair loss (Kurina et al., 2019). Besides, this fly is considered a potential vector for several pathogens. In fact, the presence of *Coxiella* spp., *Theileria luwenshuni* and *T. ovis* have been detected in some fly specimens, though its role in the transmission of other agents (*Babesia* spp., *Hepatozoon* spp., *Anaplasma* spp., *Ehrlichia* spp., *Rickettsia* spp., *Bartonella* spp., *Borrelia* spp.) has not been clarified (Lee et al., 2016). For this reason, further investigations are needed to verify if the parasite acts as biological vector for pathogens, as well as which effect it can produce on the host (Reeves and Lloyd, 2019).

***Lipoptena mazame* Rondani, 1878**

The species has been recorded in the south-eastern United States and several central and south America countries (Reeves and Lloyd, 2019; Skvarla and Machtinger, 2019). This parasite infests mainly Mazama deer in central and south America and white-tailed deer in the United States, but the fly may accidentally parasite pampas deer, domestic cattle, pumas and humans (Reeves et al., 2006; Graciolli et al., 2011). Recent studies have proved that *L. mazame* acts as vector for *Bartonella* spp. Every year *B. henselae* is responsible for over 20,000 human infestations in the United States; its main vectors are domestic cats, but the presence of this pathogen has been detected in *L. mazame* as well (Reeves et al., 2006). Moreover, the fly may transmit *B. schoenbuchensis*, which is well-known to cause deer ked dermatitis in humans, and it is implied also in the transmission of *Anaplasma* spp. in cattle and *Trypanosoma cervi* in cervids (Reeves et al., 2006; Trout et al., 2010).

***Melophagus ovinus* (Linnaeus, 1758)**

This parasite is an important economic species of sheep. Adults are wingless (Fig. 12), 4–7 mm long brown colored (Yevstafyeva et al., 2017). *Melophagus ovinus* is distributed in the major part of temperate and subtropical areas where sheep are bred. The life cycle of the parasite is completely carried out on the host: gravid female generates a creamy fully grown larva which is attached to the host wool by means a glue-like secretion and in few hours it molts in a dark puparium. A single female can generate up to five-six larvae and the pupal stage lasts about 19–30 days in relation to the temperature. Even if the species is wingless it can switch from one host

Fig. 11 *Lipoptena fortisetosa* adults. Female (A) and male (B). Modified from: Andreani A, Sacchetti P, Belcari A (2019) Comparative morphology of the deer ked *Lipoptena fortisetosa* first recorded from Italy. *Medical and Veterinary Entomology* 33: 140-153.

Fig. 12 *Melophagus ovinus* adult.

to another very easily, especially from the mother to lambs (Small, 2005). A study conducted on Wyoming unshorn lambs to investigate the distribution of keds over the bodies, showed that the most colonized area of the host was the rib for both sexes of the ked, while the next most heavily populated area for the males was the thigh. Ked populations increased in winter and spring, with an average of 400 keds/host approximately, decreased in summer and increased again in the autumn (Legg et al., 1991).

The number of infesting keds on the sheep can vary a lot: in Ukraine the mean number of the keds/host was 92.72 (Yevstafyeva et al., 2017), while in Canada the mean number was higher. In fact, the peak populations for barren ewes ranged from 61 to 659 keds and for pregnant ewes from 110 to 1348 keds; anyway a general reduction of keds in all animal categories was noticed (Nelson and Qually, 1958). Reduction of the populations seems to be due to several factors such climatic conditions, physiological status as well the intrinsic resistance of the hosts. This latter has been fully investigated in some experimental trials and it has been proved that sheep during the time develop a resistance to the insect trophic activity in terms of inflammatory response to keds. This resulted in changes to the skin that reduced the keds' ability to feed successfully. In other words, the development of resistance was at the beginning, determined by the frequency of attempts for the feeding activity as well the ability and time taken to engorge (Nelson and Kozub, 1980). Later, investigations carried out on artificially infested lambs showed elevated antibody titres within 5 months after the infestation which reached the maximum peak. Further experiments highlighted that the resistance was temporary and mainly due to an inflammatory response to the skin lesions produced by the keds activity as the direct result of the localized arteriolar vasoconstriction that makes blood unavailable to the keds (Baron and Nelson, 1985; Nelson and Kozub, 1980; Small, 2005).

Presence of keds on the host causes a skin reaction such as pruritis, aggravated by the rubbing and scratching in response to the irritation, with consequent reduction of growth rates and production. Besides, losses of the leather quality due to the nodules produced by the keds feeding activity have been observed (Legg et al., 1991; Small, 2005).

Melophagus ovinus is a species of veterinary and medical importance since it is a vector of some important diseases. A recent study conducted in China during the years 2013–17 aimed at investigating the presence of pathogens inside the sheep flies, showed as primary result, the detection of *Anaplasma ovis* DNA in pupae, confirming the potential vertical transmission. *Anaplasma ovis* is an obligate pathogen infecting sheep, goats, and some wild ruminants and its presence in animals causes the anaplasmosis which is an important disease for public and animal health producing economic losses to sheep breeding (Zhao et al., 2018). Moreover, *M. ovinus* is capable to transmit the Blue Tongue Virus (Luedke et al., 1965) as well as the Border Disease Virus, which is an important infection in sheep and goats (Liu et al., 2019). In a survey carried out in Ethiopia, on different domestic animals, it has been shown that about 86% of keds collected from sheep were infected by *Acinetobacter lowfii*. *Acinetobacter* spp. are ubiquitous bacteria implicated in different types of human infections especially in immunocompromised individuals (Kumsa et al., 2013). Halos et al., 2004 demonstrated the vertical transmission of *Bartonella* in *M. ovinus* due to the presence of *Bartonella* DNA in all sampled pupae of the sheep ked, suggesting a symbiotic association between the bacterium and the vector. Further researches allowed the identification of this bacterium as *B. melophagi* (Kumsa et al., 2013; Liu et al., 2018). Finally, some authors demonstrated the presence of *Borrelia burgdorferi* and *Rickettsia* in different sheep ked samples (Chu et al., 2011; Liu et al., 2016).

Management strategies for the sheep ked

Shearing practice can reduce about 75% of the ked population; ewes have to be shorn prior to lambing, otherwise keds can move from them and infest later their lambs. Unshorn lambs, until the following spring, could become a reservoir of infestation for the flock (Johnson, 2011).

Topical application of chemical insecticides is a spread practice and spray, or dust are usually applied in ked control programs. Best results have been obtained treating sheep after shearing; the replacement of animals should take into consideration to treat them before introducing into the flock. It is important to keep treated animals away for about 7–10 days in order to allow the insecticide to kill all the external parasites. Best results in the treatment procedures have been obtained by the application pour-on of permethrin plus piperonyl butoxide (Johnson, 2011) or diazinon and cypermethrin that showed, in addition to a remarkable effectiveness, a long-lasting preventive action (Small, 2005).

Neolipoptena ferresi Bequaert, 1935

This is the only species of *Neolipoptena* genus (Dick, 2006). It is a volant fly infesting predominantly Cervidae, to a lesser extent Bovidae, and occasionally humans (Hutson, 1984). It is well-represented in western America and occurs in the same areas of *L. depressa*. The species is considered a potential vector for *Anaplasma* spp. (Skvarla and Machtinger, 2019).

Subfamily Ornithomyinae

Crataerina pallida (Latreille, 1812)

The “swift louse fly” is a monoxenous ectoparasite, so named because commonly collected on the European swift (*Apus apus*) and, to a lesser extent, on martin (*Delichon urbicum*) (Hutson, 1984). This hippoboscids is widespread in the Palaearctic region, although its populations are decreasing due to the decrement of host species. (Oboña et al., 2019). An interesting trait of this hippoboscids is its scarce fly ability caused by reduced forewings unsuitable for this activity (Liu et al., 2019). However, it is agile inside the plumage and establishes a permanent association with a single host, adapting its life cycle with the bird seasonality. Since the swift is a migratory bird usually returning to the same places every year, *C. pallida* lays larvae directly in or around the nest and dies when birds leave the nesting site to migrate back to Africa. The new adult emergence, occurring after a dormant period until the next breeding season, coincides with host return (Bequaert, 1953; Hutson, 1984). Currently, this hippoboscids has been studied for its interesting morphological and physiological adaptations, mainly for its capability to remain adhere to the victim which is able to reach altitudes exceeding 3500 m and velocities faster than 40 km/h (Petersen et al., 2018; Liu et al., 2019). Differently to *Pseudolynchia canariensis*, *C. pallida* attacks mainly adult instead of young swifts; it has been recorded with a density of maximum 31 parasites on a single host subject (Hutson, 1984). Nevertheless, damaging effects have never been detected on hosts, although the parasite can remove up to 5% of the host's blood volume (Liu et al., 2019). Recently, this species has been proved as a potential vector of *Rickettsia bellii* and *R. monacensis*, suggesting its role in the transmission or in the spread of these pathogens (Cerutti et al., 2018).

Icosta americana (Leach, 1817)

The species belongs to the Nearctic genus *Icosta*, which is the largest of the Hippoboscidae family (Hutson, 1984). This fly is a parasite of owls, which can be infested from a single individual to more than 12 specimens. *Icosta americana* has been identified as a possible vector of West Nile Virus (Gancz et al., 2004). Positive specimens, both unengorged or with blood, have been collected from positive owls in Pennsylvania and in Canada in Ontario (Farajollahi et al., 2005). Although the competence of the vector has not been confirmed yet, it is particularly worthy of attention that some positive parasites were unengorged. It suggests that further investigations are needed to understand the role of *I. americana* as a carrier for the virus.

Pseudolynchia canariensis (Macquart, 1840)

This parasite is known as the “pigeon louse fly” because it is generally associated with tame or wild pigeons, and doves; it is the only hippoboscids attacking domestic birds (Bequaert, 1957; Maa, 1966). This species shows the highest affinity for its host, *Columba livia*, (Fig. 13) although it has been found on other birds, such as Falconiformes (Hutson, 1984; Yamauchi et al., 2011; Santos Murgas et al., 2014). The fly is present worldwide, in tropical, subtropical and temperate areas, where its host occurs. *Pseudolynchia canariensis* can attack occasionally humans, but it happens rarely, in case the parasite has lost the pigeon and encounters humans nearby. The bite is a painful annoyance for humans, but the fly seems to not transmit any diseases to them (Kern, 2014); however, *C. livia* is a reservoir for zoonotic pathogens, which means that the parasite could play a significant role in the transmission (Amaral et al., 2013). This hippoboscids is known to cause several health problems to the hosts, such as skin irritation or dermatitis. Moreover, it is a potential carrier for *Haemoproteus columbae* an avian malaria parasite highly dangerous for young birds and able to make hosts more susceptible to predation (Earle et al., 1993; Pirali-Kheirabaldi et al., 2016). It is well-known that the fly infests

Fig. 13 *Pseudolynchia canariensis* on the external plumage of a feral pigeon, *Columba livia*.

Fig. 14 Abdomen of *Pseudolynchia canariensis* with phoretic mites.

more frequently young subjects instead of adults, probably due to the immunity acquired by adults, which additionally use claws and beak as defense weapons against parasites (Amaral et al., 2013). Besides, *P. canariensis* can potentially transmit *Trypanosoma hanna* and DNA of *Bacillus burgdorferi* has been detected in this species as well (Nartshuk et al., 2018). The pigeon fly establishes phoretic association with mites (Fig. 14) (particularly genus *Myialges*), chewing lice and Mallophaga as reported by Maa (1966), Macchioni et al. (2005), Amaral et al. (2013), and Kern (2014).

Subfamily Hippoboscinae

Hippobosca equina Linnaeus, 1758

Hippobosca equina is a medium-sized hippoboscid species, spread in several temperate areas of the Palearctic and West Oriental Regions (Sóos and Hurka, 1986). The fly is an obligate parasite that feeds on several mammal host species, primarily on domestic horses. The species can reproduce also on cattle (Maa, 1969; Hutson, 1984) or on different secondary hosts such as red deer (Kadulski, 1996), camel and rabbit (Maa, 1969). Further, also birds such the grey heron (Olafsson, 1985) and northern goshawk (Kristofik and Stefan, 1980) have been recorded as occasional hosts. The species is commonly termed also “forest fly.” Wings

Fig. 15 *Hippobosca equina*. Adult (A) and typical wing pattern (B).

(Fig. 15) display a vein reduction typical of nearly all representatives of the family, but primary veins remain hardened allowing the adults to fly very fast and also for a long time (Turner and Mann, 2004). Gravid females larviposit a full-grown larva in suitable sites, mostly in organic litter (Roberts, 1925). Main biological information for this species have been given by Hafez et al., 1977, which report that *H. equina* was reared artificially in Egypt on guinea pigs. Main results relied on some physiological features of lab-reared adults who survived up to 40–44 days when fed on the blood of factitious hosts and only 1–2 days when starved. The female fecundity ranged from seven and nine larvae during the entire life and the duration of intrauterine life of the larvae lasts from 3 to 8 days according to different climatic conditions. A 2-year study carried out in Poland on primitive horses showed that *H. equina* was present in this area mainly with highest presence from mid-June to the end of July and the most attacked horses were working geldings, leading stallions, and 1.5-year-old colts (Sokoł and Michalski, 2015).

Hippobosca equina is a potential vector of some important animal diseases such as the haemopathogen *Anaplasma* spp. on horses in Tunisia (Selmi et al., 2019) or the Buffalo Oedematous Skin Disease (OSD) produced by *Corynebacterium pseudotuberculosis equi* which cause closed skin lesions either oedematous or nodular or open ulcerative lesion in buffaloes in Egypt (Arafa et al., 2019). In a research carried out in France in several specimens of *H. equina* the intracellular Gram-negative bacterium *Bartonella comelii* has been detected and identified (Halos et al., 2004). *Bartonella* spp. are considered to be emerging pathogens in humans and animals and are present in a wide range of wild and domestic mammals, some of which have been associated with zoonoses (Breitschwerdt and Kordick, 2000; Chang et al., 2000; Halos et al., 2004).

Some anaphylaxis cases due to the bite of *H. equina* to humans have been described. In South America, a man 54-year-old showed severe reactions developing generalized pruritus, followed shortly by generalized urticaria, palpebral and labial oedema, dyspnoea, and hypotension after a bite of *H. equina* (Vidal et al., 2007). In Italy a 48-year-old female showed after a bite a generalized pruritus and then extensive urticaria, abdominal pain, nausea, angioedema on the face, and dyspnoea (Quercia et al., 2005). Finally, in Hungary a 46-year-old female patient showed different symptoms such as hard swelling at the border of the forehead, with oedema. After, erythema and itching developed locally and all over the body, with oedema in the hands, face and lips, later accompanied by shivering, nausea and vomiting (Decastello and Farkas, 2010).

***Hippobosca longipennis* Fabricius, 1805**

Hippobosca longipennis is a common hippoboscid species spread in several countries of southern Europe, Africa and Asia, particularly China and India, associated especially to arid and semi-arid areas. This parasite is frequently called “dog fly,” because wild and domestic dogs are its principal victims, and it has been found also in mummified dogs in Egypt (Sokoł and Gałęcki, 2017). However, it has been collected from different other species, such as fox, cat, hyena, cheetah, lion mongoose or civet (Megat Abd Rani et al., 2011; Reeves and Lloyd, 2019) and occasionally from humans (Bequaert, 1942). *Hippobosca longipennis* is considered the main vector of the filarial nematode *Acanthocheilonema dracunculoides*, found in several European countries in different host species. Moreover, the involvement of this fly as vector of the filarian nematode *Acanthocheilonema* spp. has been proved in northern India (Megat Abd Rani et al., 2011; Mihalca et al., 2019). The health importance of this nematode seems to be little, with just one case in Australia: a female larva was detected in a human eye (Megat Abd Rani et al., 2011), but further investigations are needed to better know its implications. The transmission occurs through the parasite bite, since the infective larvae migrate from the fat-body cells to the mouthparts of the fly. In addition, *H. longipennis* can have a phoretic association with the mite *Cheyletiella yasguri*, zoonotic agent harmful for dogs and humans since it can cause itching, erythema and exfoliative dermatitis (Megat Abd Rani et al., 2011; Sokoł and Gałęcki, 2017).

Bat flies (Nycteribiidae and Streblidae)

Bio-taxonomy, morphological adaptations and behaviour

Bat flies are a highly specialized group that includes two families, Streblidae and Nycteribiidae, both strictly limited to bats (Dick and Patterson, 2006). A total of 520 recognized species belong to the bat flies, making this group the richest of species among the Calyptate Diptera related to mammals (Dittmar et al., 2006). Although they are spread worldwide, no species, genus or even subfamily are present in both hemispheres; in fact, streblids are well-represented in the Western Hemisphere, while nycteribiids are common in the Eastern (Dick and Patterson, 2006). Two subfamilies among the Streblidae (Nycteriboscinae, Ascodipterinae) are well-represented in the Old World, while the other three (Trichobiinae, Nycterophilinae and Streblinae) have been recorded mainly in the New World (Petersen et al., 2007). Bat fly families occur in different climate areas as well: Nycteribiidae occupy temperate regions, while Streblidae have been found in tropical and subtropical climates (Dittmar et al., 2006).

Life cycle of bat flies seems to be quite similar to that of hippoboscids, and it is likely the same among species (Peterson and Wenzel, 1987). All of them live in close association with their hosts inside caves together with gregarious bats and show a high level of host specificity although different bat species occupy the same sites (Lourenço and Palmeirim, 2008). About every 10 days, females leave the infested subject to stick on roost walls a single larva, and then actively search for a new host. Since males do not lay larvae, it could be thought that they always stay on the victim, but, actually, several male flies have been collected from cave walls, proving that they leave the host at least for brief periods (Dick and Patterson, 2006). Several factors affect host specificity in bat flies, for example climate conditions, isolation, competition or predation, and morphological or physiological adaptations (Autino et al., 2011). Bat flies are monoxenous or stenoxenous, and, although they are able to infest alternative bat species that live in the same cave, their preference in parasitizing one species have been demonstrated recently (ter Hofstede et al., 2004; Lourenço and Palmeirim, 2008; de Vasconcelos et al., 2016). Host specificity presumably is affected also by fly ability, but, despite of nycteribiids are totally wingless, they are as specific as the winged streblids (ter Hofstede et al., 2004). Different parasite species can infest the same subject, and the presence of several flies at the same time on a single host has been proved positively associated (Dick and Patterson, 2006).

Bats are the first cause of parasite death. In order to avoid the predation during host auto-grooming behaviour, flies adapted to occupy specific micro-niches, in fact, they generally are located on the pelage or under the membranous wings of bats (ter Hofstede et al., 2004). Moreover, they move very fast in all directions and have structures, e.g., claws, that allow them to adhere to the host (Dick and Patterson, 2006; Kim et al., 2012). Bat flies have a peculiar general morphology, and, like the other Hippoboscoidea, they display several adaptations that make them able to efficiently live together with the hosts (Peterson and Wenzel, 1987; Wenzel and Peterson, 1987). Nycteribiidae evolved the same structures, while, among Streblidae species, morphological adaptations are more variable. Differently from Hippoboscidae except for *Melophagus* spp., bat flies have reduced or absent compound eyes due to an evolutive response towards the dark environment in which they live (Mayberry, 2014). Despite the two families show several common characteristics in both morphological and bio-ecological traits, they have been divided in two groups because of differences in some body structures and in their geographical distribution (Table 1).

Table 1 Main differences between the families Nycteribiidae and Streblidae.

	Body	Head	Wings	Legs	Distribution	Climate
Nycteribiidae Nycteribiidae	Dorsoventrally flattened; spider-like	Backwardly folded at rest	Absent	Dorsally inserted	Eastern hemisphere	Temperate regions
						
Streblidae Streblidae	Varying from generalized convex, laterally compressed to dorsoventrally flattened; flea-like	Prognathous	Fully developed, brachypterous, stenopterous, or apterous.	Laterally inserted	Western hemisphere	Tropical and subtropical regions
						

Subfamily Ascopterinae

Genus *Ascopteron* Adensamer 1896

Members of this subfamily are distributed in tropical and subtropical areas especially in Africa, Middle East, Asia and Australia (Wenzel and Peterson, 1987). *Ascopteron* spp. represent the only exception to the ectoparasitic nature of bat flies. After mating, an eyeless female embeds herself in the tissue of the host thanks to a strongly modified mouth apparatus that has series of cheliceral blades located at the tip of the labial thecum (Hastriter et al., 2006), and becomes an endoparasite (Wenzel and Peterson, 1987; Dick and Patterson, 2006). When she settles on a host, immediately sheds wings, halteres and all legs except for coxae; moreover, thorax and mouthparts invaginate within the abdomen forming a cyst-like body. This feature is a rare example of neosomy in the adult stage; in fact, there is an additional cuticular secretion that allows the enlargement of the whole abdomen. This latter protruding from the host skin displays three pairs of respiratory spiracles close to the anal opening (Hastriter et al., 2006).

Health importance of bats and bat flies

Bats are a great diverse mammalian group, second only to rodents. They play an essential role in ecosystems and have also public health significance (Szentiványi et al., 2019). In fact, bats are known to be reservoirs of several etiological agents, such as Rabies, Marburg, Ebola, measles, mumps, parainfluenza, canine distemper and hepatitis C viruses (Han et al., 2015; Reeves et al., 2016). For many reasons these animals are likely carriers of pathogens, they are the second largest order of mammals with a high diversity of species and a long evolutionary history allowing the co-evolution with viruses. Moreover, bats are social animals that create aggregation of millions of subjects, they are able to fly long distances facilitating the spread of agents and have a relatively long-life span (Han et al., 2015). Bats are hosts for many different ectoparasites, among which Nycteribiidae and Streblidae flies are the most common. These parasites have been implicated as vectors of several pathogens, like protozoa (*Nycteria* spp.), arboviruses and trypanosomes (*Trypanosoma vespertilionis*). In addition, nycteribiids are able to transmit *Polychromophilus* spp., while filarial nematode DNA have been detected in streblids, although it is not clear if it is only present in the last blood meal (Reeves et al., 2016; Szentiványi et al., 2019). DNA of *Bartonella* spp. was detected in *Trichobius major* (Diptera: Streblidae), demonstrating that it may play a role in the transmission of the agents but not explaining the competence of the vector (Reeves et al., 2005). Bat flies more host specific display a lower diversity of *Bartonella* spp., but a general high prevalence of these pathogens, suggesting they have co-evolved with bats. Viviparity could cause vertical transmission of agents from the mother to the offspring through the “milk glands” (Szentiványi et al., 2019). Finally, parasites can affect host behaviour, inducing bats to change roost in case of a high pupal density on the walls. Moreover, a high infestation level can reduce the survival and the reproduction success of the host (Szentiványi et al., 2020).

Concluding remarks and challenges for further research

After this literature analysis and critical discussion on keds, louse and bat flies, it is clear that much work has been done in these last years especially for the detection and identification of pathogens carried by these parasites, proving in some cases that they could play an important role as vectors of etiological agents responsible of diseases in both animals and humans. Investigations have been carried out thanks to new molecular tools allowing the identification of the species as well of the different strains of pathogens. Nevertheless, we have to stress the importance of future basic studies on these flies mainly concerning their morphology, biology and behaviour that may contribute to better understand the real role of these parasitic flies, particularly in relation to both wild and domestic hosts as well to the environment. Finally, it will be particularly worthy of attention the studies dealing with the possible zoonoses transmitted to humans.

Glossary

Abiotic factors Physical or chemical elements of nature that characterize a given biotope or ecosystem.

Akinesia Lack, loss, or cessation of movement.

Anthropozoonotic Disease that passes from animals to humans.

Biotic factors Factors that result from activities of a living being, or any other living component of an environment, such as how the actions of one organism affect the life of another organism.

Coprophagy Feeding on feces.

DDT Diclolo-diphenyl-trichloroethane, insecticide used in various groups of insects.

Domestic cycle When infection in humans occurs through contact with intradomiciliary insects.

Ecotope Physical medium in which a biological community develops.

Endemic That habitually affects a region or country.

Enzootic Disease that affects one or more animal species in a given territory.

Exoterygote Insect that undergoes an incomplete metamorphosis, which gradually changes from the immature to adult stages; juveniles are similar in appearance to adults, but have wings that develop externally (e.g., triatomine nymphs to adults).

Fat body Tissue in insects formed by storage cells that is distributed throughout the body cavity.

Hematophagous Feeding on blood.

Hemimetabolous Term referring to insects whose metamorphosis is gradual or incomplete, and in which the juvenile is similar to the adult or imago.

Hemocoel Unlined cavity characteristic of many invertebrates in which the hemolymph is found.

Hemocytes The cells found in invertebrate hemolymph.

Hemolymph Circulatory liquid of invertebrates, analogous to blood in vertebrates.

Holometabolous Type of development in higher insects, characterized by having distinct embryo, larval, pupal, and imago stages.

Incomplete metamorphosis Development that includes only three stages: egg, nymph, and imago.

Intradomiciliary Insects vector presence inside the home.

Metacyclogenesis When metacyclic parasites are produced. In this case, when epimastigotes become metacyclic trypomastigotes.

Paratransgenesis Technique based on the use of symbiotic bacteria to express effector molecules within a target vector.

Phytophagous Feeding on plant material.

Reservoir Long-term host of a pathogen that causes an illness.

Screening Test to detect a disease.

Symbiont Organism that lives in interaction with another organism, usually a larger one.

Vector Any agent that transports and transmits a pathogen to another living organism.
Wing primordia Rudimentary state in which a developing organ is found, in this case, the wings.
Zoonanthropnotic Disease that passes from humans to wild animals.
Zoonosis Disease found in animals that can be incidentally transmitted to humans.

Introduction: What are triatomine bugs?

The triatomines are insects of the subfamily Triatominae (Hemiptera: Reduviidae), which is composed of 149 species distributed mainly on the American continent (Justi et al., 2016; Monteiro et al., 2018). Throughout the life cycles triatomines feed on the blood of vertebrates, in other words, they are hematophagous, associated mainly with the nests of birds and small mammals (Carcavallo et al., 1999; Rabinovich et al., 2011). The triatomines, also known as kissing bugs, are vectors of the six described lineages of *Trypanosoma cruzi* (Kinetoplasta: Trypanosomatidae) (Brenière et al., 2016), the etiological agent of American trypanosomiasis or Chagas Disease. American trypanosomiasis is the zoonosis limited to wild habitats, while Chagas disease refers to the illness that occurs in humans. The landscape changes that occur in natural ecotopes have been key for the invasion and adaptation of the vectors to human dwellings, and with them, the establishment of *T. cruzi* transmission in urban environments (Parker and Sethi, 2011). The World Health Organization (WHO) classified Chagas disease as one of the 10 neglected tropical diseases that pose the greatest threat to public health (Justi and Galvão, 2017; Tarleton et al., 2014). Kissing bugs acquire *T. cruzi* when they feed on a reservoir of the parasite, which is an infected mammal (Rabinovich et al., 2011). Classic transmission of *T. cruzi* is through the triatomine's feces (Beard, 2005), though there are other mechanisms.

Past, current and future distribution of triatomines

Some underlying evolutionary questions about this group are when and where it arose, whose responses, based on molecular clocks, have reached unclear conclusions (Justi and Galvão, 2017). One of the most widely accepted hypotheses is that the triatomines arose during the Oligocene, when South America was already isolated from the Antarctic and the rest of the American continent (Hwang and Weirauch, 2012; Ibarra-Cerdeña et al., 2014; Otálora-Luna et al., 2015). Whatever their origin, populations of Triatominae tend to show similar adaptive behavior. Presumably, the triatomines evolved from predators of the family Reduviidae which diversified on the continent at the same time as mammals and birds during the Jurassic (Monteiro et al., 2018). Given that the family Reduviidae contains a wide variety of predatory behaviors (Hwang and Weirauch, 2012), it is thought that the diversification of the lineages of the reduviids could be a consequence of, among other factors, changes in feeding behaviors.

Different species of triatomines are distributed from the southern United States through southern Argentina (Fig. 1) (de Fuentes-Vicente et al., 2018). However, 14 species have been reported in the Old World: eight of the genus *Triatoma* and six from *Linshcosteus* (Monteiro et al., 2018). It is likely that the triatomines from the Old World originated in the New World (Hypša et al., 2002; Justi et al., 2016). Specifically, in Asia a common ancestor is reported to have given rise to the groups of *Triatoma* with distribution in Asia/Australasia, and the *Linshcosteus* restricted to the southern Himalayas and southeastern Thar Desert (Monteiro et al., 2018; Patterson and Gaunt, 2010). Interestingly, there is only one species that is distributed both in the Old and New World, *Triatoma rubrofasciata*, but it only has epidemiological importance in the Americas (Dujardin et al., 2015). It is suggested that ships were responsible for the dispersion of *T. rubrofasciata* (Barrett, 1991). It is worth pointing out that none of the Old World triatomine species have been reported as natural vectors of *T. cruzi* (Hamilton et al., 2012). This supports the hypothesis that the protozoan *T. cruzi* originated on the American continent (Hamilton et al., 2012).

The distribution of the triatomines on the American continent is due to their tolerance to a wide range of environments. There are biotic and abiotic factors that modulate the distribution of the triatomines. Among the biotic factors, the most important are the diversity of food sources for the triatomines (Noireau et al., 2005) and the presence or absence of infection by *T. cruzi* (Villalobos et al., 2019). In the case of abiotic factors, temperature (Carmona-Castro et al., 2018) and anthropization have favored distribution (Parker and Sethi, 2011). The use of georeferencing tools have allowed the current distribution of the subfamily Triatominae to the predicted distribution with increased detail (Gurgel-Gonçalves et al., 2012; Ibarra-Cerdeña et al., 2014). While most triatomines prefer to inhabit wild environments and the cycle of transmission of *T. cruzi* occurs among the wild mammals present there (Jurberg and Galvão, 2006), there are species such as *Rhodnius prolixus*, *Triatoma infestans* and *T. dimidiata*, that have been able to colonize and adapt to human dwellings (Jurberg and Galvão, 2006).

Medical importance

A history of humankind and Chagas disease

Chagas disease is as old as the first appearances of humans in South America (Steverding, 2014). Thanks to advances in molecular techniques, it has been possible to document the oldest known infection with *T. cruzi* in a Chinchorro mummy from 9000 years ago

Fig. 1 Distribution of Chagas disease and the main vectors in the Americas. The nuances indicate the number of cases per country. de Fuentes-Vicente JA, Gutiérrez-Cabrera AE, Flores-Villegas AL, Lowenberger C, Benelli G, Salazar-Schettino PM, and Córdoba-Aguilar A (2018) What makes an effective Chagas disease vector? Factors underlying *Trypanosoma cruzi*-triatomine interactions. *Acta Tropica* 183: 23–31.

(Aufderheide et al., 2004). The Chinchorro culture is the name given to a group that fished along the coast of the Atacama Desert in South America between 7020 and 1500 years ago (Aufderheide et al., 2004; Vigliano et al., 2020). Based on the available paleoparasitological data, it is thought that Chagas disease originated in the Andean region. In this area, patterns of socioenvironmental occupation favored the gradual transition of *T. cruzi* from the wildlife to human homes (Ferreira et al., 2011; Steverding, 2014; Vigliano et al., 2020).

The disease was not discovered until 1909, when the Brazilian physician Carlos Chagas identified it in Minas Gerais while carrying out an anti-malaria campaign (Chagas, 1909). This discovery was a milestone in the history of medicine because it simultaneously described the causal agent, some of the clinical manifestations of the disease, and the insect vectors. Previously in the literature there were reports of kissing bugs, but their epidemiological role was unknown (Steverding, 2014). Perhaps the most famous note is the anecdote by Charles Darwin in 1835 narrating the “attack” by these bugs at night, and that Darwin let one of the bugs feed on him in order to describe its morphological changes (Darwin, 1839). This has led to suspicions that the myocardial infarction that caused Darwin’s death could have been related to the cardiomyopathy produced by Chagas disease. After Carlos Chagas’s discovery, a number of studies documented the presence of triatomine bugs over much of the American continent, and the introduction of diagnostic techniques showed that *T. cruzi* infection was widespread among humans (Gürtler et al., 2008). Toward the end of the 20th century, it was estimated that there were nearly 18 million people infected with Chagas disease worldwide, a number that has decreased thanks to programs to control triatomine bugs (Noireau et al., 2009).

Epidemiology of Chagas disease

At some point in its evolution, *T. cruzi* became adapted to life in the gastrointestinal (GI) tract of triatomines, where it replicates and is expelled along with the bug’s feces and urine. Thus, triatomines become infected with *T. cruzi* after feeding on the blood of an infected host and days later expel the parasite, infecting other hosts and completing the cycle of transmission (Beard, 2005) (Fig. 2).

The vast majority of kissing bug species live in wild ecotopes and are associated with nests and refuges of small mammals and birds (Carcavallo et al., 1999; Rabinovich et al., 2011). This is how a little over 100 species of mammals (mainly rodents, edentates, and carnivores) and some species of reptiles participate in the cycle of transmission of this parasite (San Juan et al., 2020; Teixeira et al., 2009), while birds do not become infected with *T. cruzi* because their immune system is able to eliminate it (Teixeira et al., 2011).

Fig. 2 Epidemiological components of Chagas disease: the *T. cruzi* parasite, the kissing bug and the human; in an environmental context.

In wild environments, the parasite circulates between vertebrate hosts and insect vectors, resulting in a wild transmission cycle that can connect with other, non-wild environments or remain independent. According to Galvão and Justi (2015), the transmission cycles can be *enzootic* (wild cycles), when only wild animals are involved; *anthropozoonotic*, when the infection is the result of contact between humans and wildlife vectors; *zoonotic–amphixenotic*, when the infection results from contact between domesticated animals and vectors from human dwellings, or the rarest mode, *zooanthroponotic*, which refers to transmission from humans to wild animals through insect vectors from human dwellings (Coura, 2013). Thus, multiple factors influence the propagation of *T. cruzi* in human populations, basically associated with the way these populations occupy and exploit their environments (Galvão and Justi, 2015; Vaz et al., 2007). When triatomines came into contact with human dwellings (da Fonseca and Robinson, 1990), humans became one of their potential food sources and, as a consequence, humans began to participate in the life cycle of *T. cruzi* as well, known as the *domestic cycle*. While other modes of transmission of the parasite have been reported, transmission by insect vectors continues to be the most important (Coura, 2015). This is because vector transmission is virtually impossible to eradicate, since it occurs in two scenarios: (1) human invasion of wild ecotopes where the transmission cycle is active, or (2) re-infestation by kissing bugs of human settlements where they were previously eliminated by vector control campaigns. As such, transmission of *T. cruzi* to humans is clearly the consequence of anthropogenic changes to the wild environment. Other mechanisms of transmission include blood transfusions (Young et al., 2007), organ transplants (Centers for Disease Control and Prevention (CDC), 2006), congenital transmission, and ingestion of food or drink contaminated with *T. cruzi* (Filigheddu et al., 2017; Santana et al., 2019).

Chagas disease has an *endemic* distribution in 21 countries in the Americas (Guhl, 2017). Currently, it is estimated that there are 6 million people who are ill and approximately 22 thousand deaths annually in Latin America alone; with Brazil, Argentina and Mexico, the most affected countries (Fig. 1). Because of a lack of screening for *T. cruzi* in donated blood and organs, Chagas disease became a public health concern in countries that are non-endemic and that do not have vectors, such as Spain, Italy, France, the United Kingdom and Switzerland (Antinori et al., 2017; Gascon et al., 2010). Thus, the WHO (2019) estimates between 6 and 7 million people infected worldwide, indicating that the cost of an infected patient is approximately US \$474 in medical expenses, with an annual cost of US\$627.46 million worldwide. The economic costs of labor losses due to disability for Chagas patients must also be added to this cost (Lee et al., 2013). This means that Chagas disease has strong economic repercussions in endemic countries.

Chagas disease involves two important stages: an acute stage characterized by the circulation of the parasites in the bloodstream, and the chronic stage in which the parasite becomes lodged in different organs such as the heart, esophagus, and colon, where they generate complications (Nunes et al., 2018). To date there is no vaccine or effective prophylaxis against Chagas disease, though there are two drugs that, if administered in time, can eliminate the infection: Benznidazol and Nifurtimox (Meymandi et al., 2018). These antiparasitic drugs, developed nearly 40 years ago, are most effective when given soon after infection, since they act much more efficiently on parasites in the bloodstream than on the invasive form in muscle. However, these medicines can have side effects such as digestive intolerance, headache and peripheral neuropathy (Kirchhoff, 2003). As such, agents like Fexinidazole are being tested clinically as an alternative and other studies seek to redesign the doses of Benznidazol to avoid these effects (Sales Junior et al., 2017).

Biology and ecology

Feeding habits

The kissing bugs' ancestors were thought to be individual predators that in turn descended from phytophagous insects (Otálora-Luna et al., 2015). One piece of evidence that supports this idea is that the triatomines' digestive enzymes include *cathepsin* like phytophagous hemipterans, rather than *trypsin*, which is used by other hematophagous insects to degrade ingested blood (Ribeiro

et al., 2014). While blood meals are their main source of food, triatomines are able to exploit other food sources, such as plant saps, blood consumed by other insects, *coprophagy*, or the *hemolymph* of other triatomines (Díaz-Albiter et al., 2016; Garrouste, 2009; Otálora-Luna et al., 2015). The variety of habitats used by the triatomines thus facilitates their relationship with their main hosts (Bar et al., 1999).

These insects tend to feed preferentially at night, while their vertebrate hosts are asleep, and during the day they remain in *akinesia*. As such, the emergence of both chemical and physical mechanisms for locating food sources were fundamental for this nocturnal behavior (Otálora-Luna et al., 2015). In the absence of light, they are able to perceive chemical signals of their hosts, including CO₂, isobutyric acid, 1-octen-3-ol ammonia, and L-lactic acid (Lazzari et al., 2013). While attraction to CO₂ is crucial for other hematophagous insects, it is apparently not as important in the process of attraction of triatomines. Curiously, after long periods of fasting there is no increase in their responsiveness to CO₂, but after a recent blood meal it acts as a repellent (Lazzari et al., 2013). The most important physical signal for triatomines is heat, and their extreme thermal sensitivity allows them to perceive thermal energy on the order of only a few $\mu\text{W}/\text{cm}^2$ from several meters away (Lazzari, 2009). In addition to its role as an orientation signal, heat is used to locate blood vessels of the host in order to feed more efficiently (Ferreira et al., 2007).

Their mouthparts are relatively small compared to other hematophagous insects, so the suction of blood must be efficient in terms of speed. For this, they have a suction pump located along the head that functions with muscles that occupy much of the head (Lehane, 2005). Once feeding begins, there is a release of the neurotransmitter serotonin into the hemolymph, which leads to the plastification of the cuticle and allows the abdominal tegument to stretch to accommodate large quantities of blood in the anterior midgut (Orchard, 2006; Sant'Anna et al., 2017). Then, the blood is digested gradually, depending on the individual's physiological requirements, allowing these bugs to endure long periods of fasting.

Individual nutrition plays a crucial role in the life cycle of the triatomines. Both sexes feed on vertebrate blood during all five nymph stages and as adults. Advantageously, triatomines are able to obtain a single feeding without suffering fitness costs (Martínez-Ibarra et al., 2018). If the amount of blood is sufficiently large, the distension of the body wall can produce a nerve stimulus that triggers the molt to the next stage. Poor nutritional condition has two developmental consequences: they take longer to molt from one stage to the next, and females produce fewer eggs (Castillo and Wolff, 2000).

If they are not disturbed during feeding, the ingestion of the complete blood meal can take between 10 and 20 min, depending on the species (Sant'Anna et al., 2017). The amount of blood ingested can be several times the bug's body weight and nymphs in the first stages consume the most blood. After a large meal, triatomines can spend several weeks without feeding, hiding in a refuge until their next feed or, in the case of adults, searching for a mate in order to breed. Triatomines in all developmental stages occupy the same general habitat and feed on the same hosts, which makes them susceptible to acquiring *T. cruzi* and remaining infected during their whole life cycle.

Life cycle

Triatomines can be observed in several different ecological scenarios. Some species are exclusive to a particular habitat or host, while others are found in different habitats (Gaunt and Miles, 2000). While habitats are diverse, all kissing bug species are limited in their tolerance to humidity (30–80%) and temperature (24–28 °C). The life cycle of these insects tends to take longer at lower temperatures (i.e. 16 °C), while temperatures above 40 °C are lethal (de Fuentes-Vicente et al., 2017; Pimentel-Melo et al., 2020).

Diverse species of vectors adapted to human dwellings are generally easy to breed in laboratory conditions, providing models for studies of their biology, physiology, genetics, and basic evolutionary tendencies (Ryckman, 1952). We know that at temperatures between 20 and 30 °C, development takes approximately 5–6 months, but this time can vary depending on the species. For example, the mean duration of the life cycle of *Rhodnius prolixus* and *Triatoma infestans* is a few months, while species like *Triatoma dimidiata*, *Panstrongylus megistus*, *Dipetalogaster maximus*, can take more than a year (Gorla and Schofield, 1989; Guarneri et al., 2000; Lima et al., 1992). These interspecific differences are probably related to different environments. For example, while *R. prolixus* lives in tropical habitats with constant environmental characteristics, this is not the case for *D. maximus*, which lives in southern Baja California (Jiménez and Palacios, 2002).

The triatomines are *exopterygotes*, which pass through different developmental stages, undergoing an *incomplete metamorphosis*. They have an egg stage, five nymph stages, and a reproductively mature adult stage (Fig. 3). Their sizes vary from 5 to 40 mm, but the most important species in the epidemiology of Chagas disease are around 20 mm (Bello-Bedoy et al., 2019; Berenger and Parola, 2017). Their eggs have an ellipsoid shape and they have an operculum. It is suggested that the geometry of the outline of the eggs could help discriminate not just among species, but also microhabitats of communities (Catalá et al., 2017). The eggs are white when laid, and by 2–3 weeks after laying are pinkish (Fig. 3) and are ready to hatch as nymph 1, which takes between 10 and 40 days after oviposition (Catalá et al., 2017). Nymphs can be differentiated from adults by their incompletely developed wings and genitalia. Between the fourth and fifth stages of development, the *wing primordia* are already visible. In the adult, the wings are completely developed, and genital differentiation is evident (Fig. 4). The internal male reproductive structures have been well characterized and are informative for taxonomic studies, particularly for distinguishing closely related species (Gonçalves et al., 2013; Pereira-Lourenço et al., 2013; Tellez-Garcia et al., 2019). On the contrary, female genitalia have been relatively little studied, mainly because it has been assumed that this characteristic is highly uniform among species and lacks taxonomic characters (Lent and Wygodzinsky, 1979; Tellez-Garcia et al., 2019).

Fig. 3 Life cycle of the kissing bugs (Triatominae).

Reproduction

Because most studies on the reproductive behavior of triatomines have been done under laboratory conditions, little is known about their reproduction in nature. It is suggested that the beginning of mating is mediated by chemical signals (Pontes et al., 2008, 2014; Zacharias et al., 2010), since triatomines do not emit auditory signals and there is virtually no visibility at night (Manrique and Lorenzo, 2012; Pontes and Lorenzo, 2012). In some species, mating in captivity occurs at night at the beginning of *scotophase*, when movement activity reaches its maximum and females leave their refuges (Lazzari, 1992; Pontes and Lorenzo, 2012). Some species of triatomines carry out precopulatory behaviors such as dances or nuptial movements that precede copulation (Galliard, 1936; Hase, 1932) or a type of courtship like female stridulation (Jiménez and Palacios, 2002). The triatomines are apparently polygamous, and mating behavior appears to be very similar among species (Manrique and Lorenzo, 2012). According to the literature review by Tellez and collaborators (2019), there are several steps during copulation reported in several species (Fig. 5). Once a male detects a female, he approaches and adopts a vigilant posture. Then, he mounts and jumps on top of her, and in some species, turns around on top of the female. If the female is receptive, the male grabs on with his three pairs of legs while he places his

Fig. 5 Mating of kissing bugs (Triatominae): (A) the male locates the female and jumps on her, (B) the male holds onto the terminalia of the female and (C) copulation occurs; (D) when copulation is complete, the male descends.

body in ventro-lateral position. After that, the male holds onto the terminalia of the female and the copulation takes place. Finally, when the copulation is completed, the male again mounts the female then descends. Copulation duration is highly variable among species; *D. maxima*, *T. brasiliensis* and *T. infestans* are the species with the fastest copulation times, lasting about 6 min, while in *R. prolixus* copulation takes 49 min on average (Jiménez and Palacios, 2002; Manrique and Lazzari, 1995; Pontes et al., 2008; Vitta and Lorenzo, 2009). Females can obtain a single copulation or up to 27, like in *T. brasiliensis*, after which the female begins to oviposit (Brasileiro, 1982). The eggs are deposited between 10 and 30 days after a successful copulation. Eggs are not adhered to the substrate, except for some species of the tribe Rhodniini (e.g. *R. prolixus*).

Immune system of kissing bugs

Triatomines may come into contact with microorganisms through food, wounds, copulation, etc. Any immune response assumes that the host recognizes the invader as non-self. The immune response implemented by triatomines has evolved through interactions with a variety of pathogens and parasites (e.g. bacteria, viruses, fungi and protozoa), with which they have been in contact during all stages of their life cycles (Flores-Villegas et al., 2015). The immune response of these insects, indeed, of nearly all organisms, is conformed of (Fig. 6): physical barriers (i.e. the cuticle and the epithelium), cellular responses (i.e. phagocytosis, nodulation, aggregation of hemocytes and encapsulation), and humoral factors (i.e. lectins, antimicrobial peptides (AMPs), and the phenoloxidase cascade (PPO)).

Physical barriers

The cuticle and the intestinal epithelium are the main lines of defense (Moussian, 2010). Both are conformed mainly of chitin fibers embedded in a matrix of proteins, lipids, and glycoproteins (Andersen, 2010). In particular, glycoproteins cover the GI tract of triatomines, particularly in the intestinal region (Gutiérrez-Cabrera et al., 2014). These glycoproteins, that is, proteins with different sugar residues, are a main component of the perimicrovillar membrane (PMM), analogous in function to the peritrophic membrane of other insects (Gutiérrez-Cabrera et al., 2016). While the PMM functions as a physical barrier and for nutrient absorption, the diversity of glycoproteins present serves as a mechanism for interaction with the microorganisms present, including both the microbiote and pathogens, such as *T. cruzi* (Buarque et al., 2016; Gonzalez et al., 2006). It has been tested whether the PMM is essential for establishment and replication of *T. cruzi* in the vector (Alves et al., 2007; Cortez et al., 2012; Garcia and Azambuja, 2004; Gutiérrez-Cabrera et al., 2019).

Cellular response

Once the pathogen evades the first line of defense, the immune cell and humoral mechanisms are activated, which often act together in response to pathogens. Pathogen recognition begins at pattern recognition receptors (PRR) which identify pathogen-associated

Fig. 6 Overview of the insect immune response. This is divided into cellular and humoral response.

molecular patterns (PAMPs; Gillespie et al., 1997). This mechanism allows the insect to recognize and respond to the pathogen more effectively in secondary encounters (Cisarovsky et al., 2012; Flores-Villegas et al., 2015). The cellular immune responses typically generate phagocytosis, nodulation and encapsulation (Borges et al., 2008; Hillyer, 2016). Phagocytosis is the main immune cell response in the hemocoel against small microorganisms and foreign bodies (Borges et al., 2008). Nodulation refers to hemolytic multicellular aggregates that trap large quantities of small pathogens that can then be melanized to form a nodule (Hillyer, 2016). Finally, encapsulation is the immunological process by which hemocytes bond to larger parasites, also accompanied by melanization (Hillyer, 2016). The cells involved in these processes are known as *hemocytes*, and they are also in charge of the production of humoral elements that will be mentioned below. Hemocytes in the triatomines are classified according to their structure and function (Azambuja et al., 1991a; Price and Ratcliffe, 1974), and their differentiation and the number of hemocytes produced depend on the type of pathogen, molt, blood meal and hormone action (de Oliveira and de Souza, 2003; Salcedo-Porras and Lowenberger, 2019). The most represented hemocytes in triatomines are plasmatocytes, granulocytes, cystocytes, prohemocytes, oenocytoids, giant granular cells, and adipohemocytes (Azambuja et al., 1991a). However, to date the role of each of these cell types in the innate immune response of triatomines is not known (Borges et al., 2008; de Oliveira and de Souza, 2003; Salcedo-Porras and Lowenberger, 2019).

There have been some experiments in triatomines that show how different factors modulate the cellular immune response. Such factors include production of ecdysone (Azambuja et al., 1991b; Orchard and Steel, 1980); prothoracicotropic hormone (PTTH; Orchard and Steel, 1980); abdominal distension (Ruiz et al., 2015); hemoglobin in the ingested blood (Azambuja et al., 1991b; Feder et al., 1997); eicosanoids (Garcia et al., 2004a,b); juvenile hormone (Feder et al., 1997); and platelet activation factor (PAF-Castro et al., 2009; Figueiredo et al., 2008; Machado et al., 2006).

Humoral response

Hemocytes are also involved in the production of humoral elements such as reactive oxygen species (ROS), reactive nitrogen species (RNS), prophenoloxidase (PPO) and antimicrobial peptides (AMP). The production of humoral elements is activated when the parasites are isolated for elimination or when they reach the *hemocoel* (Zumaya-Estrada et al., 2017). During the process of phagocytosis, the hemocytes release cytotoxic agents, known as a respiratory explosion, accompanied by a rapid increase in oxygen consumption (Lambeth, 2004; Rosales and Uribe-Querol, 2017). PPO in triatomines has been identified within the hemocytes (Fonseca et al., 2010; Gomes et al., 2003; Hillyer, 2016; Lu et al., 2014) and is expressed in multiple tissues (Favila-Ruiz et al., 2018;

Zumaya-Estrada et al., 2018). AMP are produced mainly in the *fat body* to be released into the hemolymph or by gastrointestinal epithelial cells to be released into the lumen of the intestine (Arrese and Soulages, 2010). In triatomines, the highly conserved AMP include defensins, lysozymes and prolixin (an atacine/diptericine type molecule), which have been described in different bug species and organs but are most common in the GI tract and fat body (Salcedo-Porras and Lowenberger, 2019). Defensins (with a molecular weight of 4 kDa) are cysteine-rich proteins, and their main role is to combat Gram-positive and Gram-negative bacteria, as well as fungi (Araújo et al., 2006; Waniek, 2009). Their mechanism of action is the formation of pores and channels that disrupt the cytoplasmic membranes of bacteria (Yi et al., 2014). Lysozymes (with a molecular weight of 15 kDa) are proteins with enzymatic activity that hydrolyze sugar residues of the peptidoglycans present in the cell walls of Gram-positive bacteria, rupturing the cell (Araújo et al., 2006; Feder et al., 1997; Flores-Villegas et al., 2015). Lysozymes can have a synergistic effect with other AMP such as cecropines and atacines (Ursic-Bedoya et al., 2008; Vieira et al., 2014) to increase antibacterial activity by degrading the bacterial cell wall (Feder et al., 1997; Kollien et al., 2003). Prolixin (with a molecular weight of 20–23 kDa) belongs to the family of glycine-rich proteins (Feder et al., 1997). Its activity is limited to a few Gram-negative bacteria (Feder et al., 1997; Ursic-Bedoya et al., 2011) in the posterior midgut, so its function may be bacterial expansion (Flores-Villegas et al., 2015; Vieira et al., 2014).

The induction of AMP expression is orchestrated by PRPs (i.e. Gram-negative binding proteins- GNBPs, and peptidoglycan recognition proteins- PGRPs), which are able to differentiate and recognize diverse microorganisms such as Gram-negative bacteria, Gram-positive bacteria, fungi and protozoa (Gottar et al., 2006; Hultmark, 2003; Lemaitre and Hoffmann, 2007). The process of microbial recognition also involves C-type lectins (CTLs; Tanji et al., 2006) and thioester-containing proteins (TEP) that bind to and mark pathogens to promote their elimination by humoral or cellular immune mechanisms (Lagueux et al., 2000). Some types of lectins are present in the hemolymph and GI tract of triatomines, where they participate in the recognition of flagellate parasites (Mello et al., 1999; Ribeiro et al., 2014).

After recognition, transduction molecules amplify this signal, resulting in the translocation of transcription NF- κ B family transcription factors (Krem and Cera, 2002) that bind to the promoters of many genes and induce AMP expression (Zumaya-Estrada et al., 2018). There are three signaling cascades involved in the expression of AMPs and with that, the elimination of invading pathogens: the immunodeficiency pathway (IMD), the Toll pathway, and the Jak-STAT pathway. In many insects, the IMD pathway is activated mainly by Gram-negative bacteria (Kleino and Silverman, 2014; Myllymäki et al., 2014), while the Toll and Jak-STAT pathways have dual function, both in embryonic development and in immunity (Lemaitre and Hoffmann, 2007), but Toll responds mainly to infection by fungi and Gram-positive bacteria (Valanne et al., 2011). The Toll and Jak-STAT pathways appear to be signaling pathways that are relatively conserved among hemipterans. On the contrary, for the IMD pathway, there is debate as to whether the pathway is incomplete or significantly reduced (Arp et al., 2016; Benoit et al., 2016; Chen et al., 2016; Saha et al., 2017; Zumaya-Estrada et al., 2018) or whether the IMD pathway is conserved in hemi- and *holometabolic* insects (Panfilio et al., 2018; Ribeiro et al., 2014; Salcedo-Porras and Lowenberger, 2019). Using molecular mechanisms (Ribeiro et al., 2014; Salcedo-Porras and Lowenberger, 2019) it was shown that the IMD pathway is actually functional in hemipterans, specifically, in *R. prolixus*, responding strongly to Gram-negative bacteria (Salcedo-Porras and Lowenberger, 2019). Despite the apparent existence of a pathway to control invasion by certain pathogens, there are experimental studies that suggest that PGRPs can activate multiple immune signaling pathways (Nishide et al., 2019). However, this is a field that needs additional research.

Triatomines and their microbiota

During the life cycle of triatomines, they are exposed to and acquire different microorganisms, especially bacteria (Balczun et al., 2008; Beard et al., 2002; Sassera et al., 2013). *Coprophyagy* is the main process by which triatomines acquire their symbiotic intestinal microorganisms (Eichler and Schaub, 2002). The acquisition of other non-symbiotic organisms can also be through coprophagy or may be associated with the environment and during the blood meal (Engel and Moran, 2013). Thus, the intestinal microbiome of the triatomines is composed of facultative and obligate symbionts, whose diversity and population dynamics (changes in growth, abundance, density, interactions, mortality and migration of each species) is little known, considering that it can vary under different physical conditions (Bolaños et al., 2016).

The microbiome of the triatomines has been described as low-complexity, with only a few dominant genera that vary depending on the species (da Mota et al., 2012; Gumiel et al., 2015), stage of development of the insect, feeding status (fasting/fed; Eichler and Schaub, 2002), food source (Dumonteil et al., 2018), intestinal region sampled (de Oliveira et al., 2018), infection by *T. cruzi* (Azambuja et al., 2005a; Díaz et al., 2016; Taracena et al., 2015) and whether the insect is wild or lab-reared (Waltmann et al., 2019). However, *symbiotic bacteria* are fundamental for the bugs' survival and development (Rodríguez-Ruano et al., 2018), participating in the biosynthesis of B-vitamins (Rio et al., 2016), homeostasis of the immune system (Mann et al., 2020; Teotônio et al., 2019), and the triatomines' ability to competently transmit *T. cruzi* (Goodrich et al., 2014; Teotônio et al., 2019).

Triatomines and *Trypanosoma cruzi*

The complete life cycle of *T. cruzi* occurs in the intestinal lumen of the insect vector and the bloodstream and nucleated cells of a vertebrate host (Azambuja et al., 2005b). There is a mobile and infectious stage known as a trypomastigote (blood trypomastigote if

bugs' immune factors linked to this are not known (Araújo et al., 2006; Ursic-Bedoya et al., 2008; Vieira et al., 2014), though bugs are known to produce AMPs such as prolixin and defensins (Moreira et al., 2014; Ursic-Bedoya et al., 2011).

The activation of the immune response imposes an energetic cost on the triatomine, which can decompensate other physiological functions like, for example, fecundity (Schwenke et al., 2016). In fact, in experimentally infected triatomines a reduction in fertility has been observed (Fellet et al., 2014), perhaps as a consequence of competition for resources between the insect and the parasite. Similarly, *T. cruzi* infection in kissing bugs delays development (Elliot et al., 2015), decreases life expectancy in adults (Cordero-Montoya et al., 2019; Schaub, 1989), decreases blood ingestion (Schaub et al., 2011) and reduces ecological niche (Villalobos et al., 2019). On the other hand, some factors, such as the vector's nutrition, food source, temperature or intestinal microbiota negatively affect the parasite (de Fuentes-Vicente et al., 2017), as well as its replication and the process of differentiation between the epimastigote forms and metacyclic trypomastigotes (metacyclogenesis) (Pimentel-Melo et al., 2020).

Curiously, *T. cruzi* also leads to physiological changes in the triatomine that may be to the parasite's advantage. For example, the levels of digestive enzymes after a meal increase (Buarque et al., 2013), which suggests that the blood consumed will be digested more quickly and the insect will need to feed again sooner, increasing the possibility of transmission of the parasite. Another similar case is that *T. cruzi* seems to promote the activation of certain immune pathways in the insect in order to decrease competition in the microhabitat of the intestine (Castro et al., 2012). All of this reveals a highly complex interaction that is the product of millions of years of coevolution between the two.

Prevention and control

By the end of the 1990s, programs to control *intradomiciliary* vectors drastically decreased the official count of the prevalence of Chagas disease in Latin American countries (Noireau et al., 2009). Vector control programs can be indirect, through housing improvement programs, or direct, using insecticides, traps, or capture of bugs inside or around the domicile (Fig. 9). The improvement of the human dwelling refers to the elimination of possible refuges for the insects to reduce the interaction between humans and triatomines. Filling in holes and cracks with cement and lime (Monroy et al., 2009) or any other material that guarantees a smooth surface (Rojas de Arias et al., 2012), has been highly effective at reducing intradomiciliary populations of some species (Monroy et al., 2009). Other interventions such as the use of screens on doors and windows are essential to prevent transient infestations (Flores-Ferrer et al., 2019; Waleckx et al., 2018). Notwithstanding, economic conditions and lack of government support in many communities have been important barriers to achieving these improvements, such that the use of lower-cost

Fig. 9 Control strategies of triatomine bugs (Chagas disease vectors).

locally available materials may be a better option (Monroy et al., 2009). Given these factors, community participation through periodic checks in houses (we suggest every 15 days) seems an ideal strategy for avoiding infestation and keeping homes free of insect vectors (Abad-Franch et al., 2011).

Dusting houses with insecticide has been widely used and is the method preferred by health authorities. Since the 1980s, organochlorate and organophosphate insecticides (such as DDT) and carbamates were the most frequently used, but they were replaced with pyrethroid insecticides due to their lower cost and larger benefits at relatively low doses (Pessoa et al., 2015). While chemical control has been an ally in the reduction of intradomiciliary populations, insect resistance and re-infestation are important factors challenging its use. Resistance results in decreased mortality in the population, which has autosomal semi-dominant inheritance (Pessoa et al., 2015). It is thought that the efficiency of dusting is lower in populations where there is a flow of individuals between domestic, peridomestic, and wild ecotopes, perhaps because of gene renewal through migration (Gourbière et al., 2012) or because it leads to the recovery of the intradomiciliary population a few months after application. New alternatives are being developed to avoid resistance and re-infestation problems by kissing bugs, with encouraging results for their potential use as vector control agents. The most studied alternatives for controlling triatomines are the use of entomopathogenic fungi, paratransgenesis by modifying symbiotic bacteria, and direct capture of the insects using traps.

Entomopathogenic fungi is an example of a technique that can kill 100% of individuals (Flores-Villegas et al., 2016) and up to 92% of eggs under laboratory conditions (Flores-Villegas et al., 2019). An advantage of this biological control method is that the most widely used fungi, *Metarhizium anisopliae* and *Isaria fumosorosea* do not appear to have adverse effects on humans, unlike the toxic effects of chemical control. However, the use of this control agent must be reconsidered since there is controversy over whether a combined effect favors the survival of triatomines infected with *T. cruzi* (Flores-Villegas et al., 2019). While these alternatives are gaining ever increasing attention, more candidates for biological control need to be considered and formulations must be viable under natural conditions.

Paratransgenesis does not attempt to kill the kissing bugs, but rather to eliminate the *T. cruzi* parasite within them and thus avoid transmission to humans (Taracena et al., 2015). The use of genetic engineering to modify triatomines' symbiotic bacteria (i.e. *Rhodococcus rhodnii*) appears to substantially reduce populations of *T. cruzi* (Fieck et al., 2010). Indeed, even unmodified bacteria, such as *Serratia marcescens* have negative effects on the parasite through the pigment prodigiosin (Genes et al., 2011). As such, the bacterial microbiome living in the GI tract or other organs of the triatomines has been investigated with the objective of limiting *T. cruzi* transmission (Buarque et al., 2016). However, the use of bacteria against *T. cruzi* in triatomines may not be feasible given that bacterial taxa vary among kissing bug species and even between developmental stages in the same individual (Oliveira et al., 2018).

The use of traps has not been particularly relevant for the control of kissing bugs and their use has apparently been focused mainly on trapping live insects for research. Some models of traps use live baits or adhesive surfaces to attract or capture the insects (Angulo and Esteban, 2011; Noireau et al., 2002). Other models have replaced live bait with attraction molecules, such as CO₂ or semiochemicals (Abad-Franch et al., 2011; Cardozo et al., 2020), both related to feeding, without yet exploring molecules related to sexual behavior. Light traps have also been used with triatomines, but they have the disadvantage of mainly attracting hungry adult insects and other insects besides triatomines (Noireau and Dujardin, 2001). Thus, there is a need to find effective, highly specific, and economical traps that can be used for vector control in homes.

Finally, it is important to point out that population control of triatomines in any ecotope should be preceded by studies of species identification, behavior, ecology and genetic structure. The goal is to choose the best control strategy, and above all, avoid re-infestation by populations of the same species or by other secondary species that could invade the habitat (Gutiérrez-Cabrera et al., 2018).

Introduction

Bed bugs (Cimicidae) and Bat bugs (Polyctenidae) are the common names of two insect families belonging to the suborder Cimicomorpha (Hemiptera), in which both are entirely composed by hematophagous-obligated ectoparasites of homeothermic vertebrates (Henry, 2009).

The family Polyctenidae Westwood is a small group comprised of 32 species and five genera of insects that are obligate and permanent parasites living in bats (Chiroptera). There is only one genus, *Hesperoctenes* Kirkaldy, represented in the Neotropical region and the other taxa are distributed among the biogeographic regions in the Old World (Autino et al., 2009; Henry, 2009). Polyctenidae members have a narrow host-specificity among bat families but some evidence suggested they could easily colonize a new host when dispersal barriers were removed (Dick et al., 2009). The knowledge of bat bugs is poorly represented in published literature in comparison with other insect taxa that live on bats and this is also reflected by their scarce presence in museum collections, taxonomic descriptions and experimental studies (Henry, 2009; Amarga and Yap, 2017).

On the other hand, the family Cimicidae Latreille (Hemiptera) is composed of 110 species of temporary ectoparasites that feed on birds, bats, and humans (Krinsky, 2019). There are only three species of cimicids that live in close association with humans: *Cimex lectularius* Linnaeus 1758, *Cimex hemipterus* Fabricius 1803 and *Leptocimex boueti* Brumpt 1910 (Henry, 2009). Although these species are often described as human parasites, they have a wide range of hosts, which includes bats and birds as well. The geographical distribution of these species is very wide. *C. lectularius* is cosmopolitan and prefers temperate climates, whereas *C. hemipterus* is distributed in tropical and subtropical regions of the world and *L. boueti* is restricted to tropical areas of West Africa (Usinger, 1966).

Many other bed bug species can feed on humans in opportunistic host-parasite interaction. For instance, the swallow bugs *Oeciacus hirundinis* Jennyns 1839, *O. vicarius* Horvath 1912, the species that parasitize bats such as *C. adjunctus* Barber 1939, *C. pipistrelli* Jennyns 1839, *C. pilosellus* Horvath 1910, and the chicken bug *Haematosiphon inodorus* Duges 1892 are some examples of cimicids that can feed on humans as a result of the changes in their natural host or the environmental conditions (Usinger, 1966). Since multiple species of Cimicidae can inhabit the human household, accurate identification is crucial to the application of pest control practices (Usinger, 1966; Wawrocka et al., 2015; DeVries et al., 2017). It is worth mentioning that the common name of cimicid species is often formed by the name of their host (e.g., swallow or bat bugs). Herein the common name bat bug is only used to refer to Polyctenidae taxon.

Medical importance

The urban pests are those species involved in the transmission of infectious diseases to humans, habitat degradation and human wellbeing. In other words, the harmful effects of urban pests can involve not only public health but also the domestic economy and the finances of public institutions and the private sector (Harlan et al., 2008). In particular, bed bugs are a difficult urban pest to control because of their biological and behavioral characteristics. Also, their effects on health and their presence in infested environments often manifest late, which makes clinical diagnosis and detection by pest control services more complex (Potter, 2011).

In contrast, there is a lack of information about the potential risks on human health and veterinary effects of bat bugs. However, it is already known that bats could act as reservoirs as well as vectors of zoonotic agents such as *Bartonella* spp. that are commonly found in different bat species and their arthropod ectoparasites around the world (Stuckey et al., 2017). It is worth mentioning that the potential transmission of the pathogenic bacterium *Bartonella quintana*, the etiological agent of Trench fever, was evidenced in *C. lectularius* feces. Although the human body louse *P. humanus humanus* L. 1758 is the main vector of *B. quintana*, the common bed bug was able to acquire, maintain and release viable bacterium in experimental conditions (Leulmi et al., 2015). These results are

important not only to evaluate the potential vector role of bed bugs and bat bugs to transmit infectious bacteria but also for unraveling parasitism mechanisms using these hematophagous insects as a model organism (Tsai et al., 2014; Ehlers et al., 2020).

During bed bugs feeding, they inoculate saliva that contains a large load of proteins with anticoagulant and digestive function, which are potential triggers of the host-immune response (Francischetti et al., 2010). A protein involved in the transport of nitric oxide to the host tissue, nitrophorin, produces vasodilation and increased blood flow to the insect (Valenzuela and Ribeiro, 1998). However, saliva is also involved in the hypersensitivity mechanism mediated by host immunoglobulins, which causes the dermal reaction (Leverkus et al., 2006).

Cimicosis is the clinical manifestation characterized by dermatological lesions produced by bed bug bites during human sleeping hours (Rahlenbeck et al., 2016). The direct effect of cimicosis can vary from scratchy bites to maculopapular rash (Delaunay et al., 2009). However, the magnitude of the allergic reactions relies on the individual immune status. There were reported patients living in conditions of severe infestations with secondary skin infections caused by scratching that developed asthma, anaphylactic reactions, iron deficiency, and anemia (Pritchard and Hwang, 2009). Furthermore, they can lead to indirect health problems, mainly due to their action as psychosocial stressors in the form of discomfort, distress, insomnia, and anxiety in people living in places with high levels of infestation (Berenger et al., 2008; Rahlenbeck et al., 2016).

The transmission of pathogens by bed bugs remains a question that requires further investigation. So far, more than 40 species of microorganisms have been identified in their saliva, intestine, feces, and integument (Delaunay et al., 2011). For instance, resistant strains of *Staphylococcus aureus* and *Enterococcus faecium* were obtained from bed bugs collected from the residences of patients who had been hospitalized for diseases caused by these bacteria (Lowe and Romney, 2011). However, the vector capacity of bed bugs to transmit disease remains under investigation (Goddard and deShazo, 2009; Delaunay et al., 2011). The potential transmission of the hepatitis B virus and human immunodeficiency virus were studied using antigen and DNA isolation techniques from bed bug feces and hemolymph (Webb et al., 1989; Blow et al., 2001). The results revealed that the bugs were able to incorporate these viruses after feeding on infected blood, but both viruses failed to replicate their gene material as well as failed to transmit them via ovaries to their offspring.

Likewise, the role of bed bugs as a vector of the *Trypanosoma cruzi* was studied, because bed bugs and the main Triatominae vector of Chagas disease, *Triatoma infestans* Klug 1834 were found together in dwellings from the endemic zone in Argentina (Jörg, 1992). This first research showed some evidence of acquisition, replication, and transmission of *T. cruzi* in field-collected *C. lectularius*. More recently, the transmission of *T. cruzi* was assessed under in vitro conditions and raised the possibility that both *Cimex* species can act similarly as vectors of this parasite (Salazar et al., 2015; Blakely et al., 2018). One hypothesis is that the biological and behavioral similarities with the Chagas vector (species belonging to the genera *Triatoma* and *Rhodnius*), such as the excretion of feces after each blood-intake and the scratching produced by insect bites could lead to the mechanical infection in their host (Delaunay et al., 2009). However, there is not enough evidence to support the effective transmission of *T. cruzi* by bed bugs, because of experiments with mice that were bitten by infected insects did not develop the disease (Salazar et al., 2015). The potential explanation could be the lack of a sylvatic cycle (wild hosts that act as reservoirs for disease pathogens) acts as a barrier for the vector transmission by bed bugs. Likewise, insect vectors and infectious agents have a common history of co-evolution, in which their survival is guaranteed by coordinated regulation and physiological balance on both sides (Lehane, 1991).

Biology and ecology

Polyctenids are insects morphologically and ecologically adapted to develop their whole life cycle on their hosts. Their body size range between 3 and 5 mm and is dorsoventrally-flattened. They are apterous, without eyes and ocelli, have long legs and sclerotized combs that enable them to move fast through their host (Henry, 2009). The life cycle of bat bugs is noteworthy characterized by viviparity, which favors physical interaction with their host (Dick et al., 2009). The first nymphal stages occur within the female, while the three post-natal stages develop directly on the host and they can feed frequently. Because bat bug dispersal depends only by direct host-host contact, the interactions between bug and bat are assumed to be monoxenous (restricted to a single host species) (Dick et al., 2009; Amarga and Yap, 2017).

Although there are similarities between both families, the main differences are mostly related to the condition of parasitism in each group. In the case of bed bugs, the following biology description is made for the common bed bug *C. lectularius* as a candidate for the whole family. Bed bugs are wingless and oval-flattened insects, in which adults are between 3 and 5 mm in length and have a reddish-brown coloration. The nymphs are yellowish-brown and size between 0.4 and 3 mm (Fig. 1). The eggs are white and cylindrical and are attached to the substrate by a cementing substance during oviposition (Usinger, 1966).

After hatching, the nymphs pass through five stages, and each requires at least one blood intake before moving to the next stage (Davies et al., 2012). Adults ingest large volumes of blood for both their nutrition, as well as for egg production and the spermatogenesis process in females and males, respectively (Reinhardt and Siva-Jothy, 2007). Under optimal conditions, an individual can complete their life cycle in approximately 35 days and continue their adult life for more than 150 days (Polanco et al., 2011). However, the life-span time will depend on host availability, feeding frequency, lifecycle stage, and environmental conditions (Usinger, 1966).

The aggregation behavior and host searching are influenced by the circadian rhythm in bed bugs (Fig. 2). The increase in locomotion occurs in the sunset hours, which coincides with the sleep hours of human hosts (Romero et al., 2010a). Also, the emission of CO₂ by the host encourages bed bugs to leave their shelter, and the active search for the host (Wang et al., 2009). After

Fig. 1 The life cycle of *C. lectularius* consists of five nymphal-stages before molting to adults. Morphological differences between both sexes could be only recognized by the rounded-shape of the female abdomen, while it is more acute in males. All life-stages are hematophagous-obligated parasites. The figure show bed bugs recently fed (left) and insects starved for 10 days (right).

Fig. 2 Bed bugs live in groups composed of insects with different ages, feeding and mating status, and also they share space with their feces, exuviae, and dead insects. Bed bug aggregations stay hidden in crack or crevices in bed, walls, and furniture.

feeding, they return to the refuges where they remain hidden until again the stimuli emitted by the host are present (Reinhardt and Siva-Jothy, 2007).

Sexual reproduction in bed bugs includes a singular strategy, although it is also present in other species of insects and groups of invertebrates (Tatarnic et al., 2006; Kamimura, 2007; Hotzy and Arnqvist, 2009). Sexual behavior involves two well-defined evolutionary strategies: traumatic insemination and sexual conflict (Stutt and Siva-Jothy, 2001; Reinhardt and Siva-Jothy, 2007; Reinhardt et al., 2009a,b). Adults copulate several times after feeding, immediately and up to 72 h later (Stutt and Siva-Jothy, 2001). During copulation, the male pierces the abdomen of the female, as opposed to the genital opening, with the aedeagus (side and distal organ, usually even, of the copulatory apparatus of male) and then the sperm is released directly into the hemolymph (Usinger, 1966; Stutt and Siva-Jothy, 2001; Reinhardt and Siva-Jothy, 2007). This reproductive strategy is called “traumatic

insemination,” and the stress imposed on females can cause a reduction in their longevity and the inability to maintain the water balance (Stutt and Siva-Jothy, 2001; Morrow and Arnqvist, 2003; Benoit et al., 2012).

To counteract stress, females have developed the mesospermae, a paragenital structure whose function is to drive sperm to the ovaries (Reinhardt et al., 2003; Benoit et al., 2012). Although it is an effective strategy, it is also expensive for females due to the energy expenditure they perform to restore the damaged cuticle, the loss of hemolymph, and the increased risk of infection (Benoit et al., 2012). The genital tract of females is only functional for oviposition (Usinger, 1966).

Sexual conflict is given by the evasive behaviors that the female deploys against the male’s attempts to copulate (Siva-Jothy, 2006). To protect the insemination zone, the females approach the right side of the abdomen close to the substrate. However, the female was unable to perform these movements when it has fed, due to bloating and it is very slow movements. Therefore, insemination by one or more males is facilitated after the females feed and stay aggregated in the shelters.

Additionally, males attempt to copulate with other males or with V-nymphs. This behavior seems to be influenced by the similarity of size with females that preventing successful recognition between individuals of different ages (Stutt and Siva-Jothy, 2001). Insects, like many other organisms, perform movements in response to the perception of a specific stimulus. In bed bugs, the thigmotaxis (direct contact) and visual cues are prevalent in sexual behavior and suggest the absence of specific sexual pheromones that allow males to recognize their sexual partners. However, the presence of chemoreceptors in the aedeagus possibly plays a role in the recognition of females and their genital structures.

Epidemiology and worldwide reemergence

It is now clear that bed bugs are parasites of humans, although this interaction is the result of a much more complex evolutionary process. The suborder Cimicomorpha (Insecta: Hemiptera) shows a wide family diversity associated with a wide variety of feeding habits. However, the hematophagous habit is an uncommon character that is only present in three families and it has possibly evolved independently throughout the history of this taxon (Schuh et al., 2009; Weirauch et al., 2019). As a result of the independence of evolutionary patterns, there are differences in hematophagy between each taxon. As was previously described the Cimicidae and Polyctenidae families are both entirely composed of species of blood-sucking ectoparasites (Cannet et al., 2015). In contrast, the Triatomines are the unique tribe of the kissing bugs (Reduviidae) that parasitized hot-blooded vertebrates and include the species of vectors of Chagas disease. Besides, parasitism strategies are different depending on taxa. Triatomine bugs and bed bugs are temporary parasites of birds and mammals, while Polyctenidae species are permanent bat parasites (Usinger, 1966; Cannet et al., 2015).

The family Cimicidae is a monophyletic group within the Cimicomorpha and its origin dates back to the Cretaceous (115 million years). Recently, the hypothesis of bed bugs evolution has been discussed based on the analysis of phylogenetic, molecular and paleontological evidence (Roth et al., 2019).

The proposal developed by Roth et al. (2019) considers that bed bugs have emerged much earlier than bats (30 million years earlier according to the fossil record), and before the mass extinction event of K/T (Cretaceous-Tertiary limit) species. In other words, although the identity of the ancestral host of bed bugs is unknown, the bats were colonized later and independently by the different lineages of Cimicidae.

Also, the diversification of parasitism in bat hosts (specialist > specialist) and the transition to birds and humans (specialist > generalist) would have occurred because those hosts provided a constant source of food, which was guaranteed by their mode of social organization and the shared use of space in the caves where they live (Booth et al., 2015). Therefore, the ability of bed bugs to seize the ecological opportunity to colonize new hosts was made possible by their genetic variability and phenotypic plasticity that allowed them to change hosts. As consequence, the transition from a specialist ancestor to generalist species seems to be the hypothesis of host-preference, and it could also explain the remarkable ability of bed bugs to adapt to different types of hosts/blood when they are raised in laboratory conditions (Roth et al., 2019).

Additionally, the fossil record has established that the speciation between *C. lectularius* and *C. hemipterus* occurred 47 million years ago and the origins of both species are different. *C. lectularius* derives from a parasitic lineage of bats, while *C. hemipterus* originates from bed bugs parasitized birds. The interpretation of this evidence raises dissents with the hypothesis of co-evolution in the parasitic-host interaction of hematophagous insects (Lehane, 1991). Under this hypothesis, there is a direct relationship between the evolution of ectoparasites and mammal radiation, as has happened between the head lice *Pediculus humanus capitis* De Geer 1767 (Phthiraptera: Pediculidae) and the lineages of the genus *Homo* (Lehane, 1991; Reed et al., 2004). However, in both bed bug species, the divergence occurred before hominids radiation, and parasitism is the result of subsequent events.

Therefore, contact between humans and bed bugs is considered to have happened at the beginning of the Holocene (10,000 years ago), and the interaction between these species occurred intermittently due to the nomadic habits of the first hominins (Usinger, 1966; Potter, 2011). Then, the development of a social way of life and the establishment of communities in permanent villages would have fostered the most intimate and constant association between bed bugs and their human hosts.

The gradual expansion of civilization, urbanization, international trade, and travel allowed bed bugs to cross seas and geographical borders (Potter, 2011). Bed bugs have been exhumed from Egyptian archaeological sites dating back more than 3500 years BC (Panagiotakopulu and Buckland, 1999), arrived Italy in 77 years AD, in the 7th century in China, and in Germany and France in the 11th and 13th centuries respectively. In contrast, the presence of bed bugs in America was recorded from the European conquerors of the 18th century and in subsequent migratory waves (Usinger, 1966).

Bed bug populations persisted, albeit discontinuously and seasonally, around the world until the 1900s. From that moment on, the increase of the human population associated with improvements in well-being and comfort provided by the access to goods and services also had a favorable impact on this plague (Usinger, 1966). During the 1940s, the incorporation of heating systems into households led to an increase in bed bug populations. As a result, the first bed bug epidemics began in the major cities of developed countries (Johnson, 1941).

In the past, bed bug infestations were managed with home-made treatments and control practices aimed at improving the hygienic conditions. Thus, people living in poverty were often the most affected, because they had limited resources to overcome the infestation. However, as a result of the reduced effectiveness of the treatments applied, both the rich and the poor struggled constantly to control bed bugs (Potter, 2011).

The earliest report of bed bug control was recorded in the Greek and Roman literature around 400 years BC. The common practice was to hang the leg or skin of animals (rabbit, deer or bear) or by placing a container of water under the bed to keep the bed bugs away (Usinger, 1966). During the 18th century, pest control companies began to offer bed bug control services and included careful inspection as the key tool to obtain adequate control (Potter, 2011). Also, the use of plant extracts as insecticides and repellents was used in Europe and Asia. Thus, a systematized list of recommended plant species to be placed under the bed as bed bug repellent was published for the first time in China in 1758 (Wang and Wen, 2011).

The safest methods for control operators and residents, but less effective for insect control, were used combined with more harmful techniques that guaranteed the extermination of bed bugs. An example of this was the use of mercury chloride, popularly known as bed bug poison (Usinger, 1966). Although applying mercury chloride to cracks and crevices in beds and walls provided satisfactory short-term results, it was also the cause of poisoning and death for residents. Furthermore, re-infestation was recurrent due to the lack of residual effect of these insecticides (Potter, 2011).

During the 1940s, the massive use of dichlorodiphenyltrichloroethane (DDT) caused a significant decrease in bed bug populations, among other pest insects. The success of DDT was due to its mode of action, fumigant power, and long residual effect. Unlike other products that required direct contact with insects, DDT guaranteed the poisoning of bed bugs that remained hidden in their shelters thanks to their fumigant power or by contact when walking on previously sprayed surfaces (Usinger, 1966).

Recommendations provided by the USDA (1953) suggested the treatment of mattresses and bed frames with DDT. It should be noted that, in addition to its effectiveness, the use of DDT offered other advantages such as a variety of formulations, incorporated in paints or impregnated in wallpaper, and could be used in multiple points (e.g., beds, mattresses, and toys) without the requirement of personal protection, equipment or professional assistance. Also, DDT was easily accessible because was purchased in groceries with relatively low cost (Potter, 2011; Koganemaru and Miller, 2013).

The use of DDT and other organochlorines, as well as the subsequent development and application of new classes of insecticides (organophosphates, carbamates, and pyrethroids), collaborated in reducing bed bug populations until almost eliminating them, especially in developed countries. Infestations became sporadic and were relegated to poor areas due to a lack of adequate sanitation and a lack of economic resources to buy effective chemical products (Krueger, 2000).

The application of insecticides as part of pest control programs allowed the effective management of bed bugs and brought relief to society at the time. An exemplary case was the performance of research and community action teams within the framework of the "National and Patriotic Public Health Campaign" implemented by the Government of China during the period 1950–80. The program included bed bugs as one of the "four pests" (along with rodents, flies, and mosquitoes) that needed to be eradicated (Cao and Liu, 2000). Treatments consisted of the application of lindane (γ -cyclohexane; organochlorine), and then fenthion (O, O-dimethyl and O-4-methylthio-m-tolyl phosphorothioate; organophosphate), combined with physical control strategies and a community educational program. During the 1980s, with the incorporation of new active ingredients such as DDVP (2,2-dichlorovinyl dimethyl phosphate; organophosphate) and the pyrethroids deltamethrin [(1R, 3R) -3- (2, 2-dibromovinyl) -2 (RS) -2-dimethylcyclopropane carboxylate (RS) -cyano-3-phenoxybenzyl], cypermethrin [(1R S) -cis, trans-3- (2,2-dichlorovinyl) -2,2-dimethylcyclopropane carboxylate (RS) -cyano-3-phenoxybenzyl] and permethrin [3-phenoxybenzyl (1R S) cis, trans-3- (2, 2-dichlorovinyl)—2, 2-dimethylcyclopropane carboxylate], favorable results were achieved in the management of the pest (Wang and Wen, 2011).

It should be noted that the intensive use of insecticides can negatively affect the pest control program. This is because continuous exposure to the insecticide only eliminates susceptible individuals, and survivors will be those individuals who possess any insecticide resistance mechanism. Despite the forthcoming risk of insecticide resistance development in bed bugs, the problem did not seem relevant enough. In particular, because of bed bug infestations remained in developing countries and communities with socio-economic vulnerability (Potter, 2011).

Although prevention and control campaigns were implemented as public health and sanitization policies, the first reports of the potential development of insecticide resistance were published. The first official data on bed bug control failures were obtained at the Naval Station Pearl Harbor, (Hawaii) in 1947 (Johnson and Hill, 1948).

During the following years, DDT-resistant bed bugs became common in several countries (Chen et al., 1956; Busvine, 1958), probably associated with spraying homes with DDT as part of the eradication of malaria (Rafatjah, 1971). Due to the increase in cases of resistance to DDT, insecticides such as lindane, malathion, and diazinon were used as alternatives (Gratz, 1959). However, the health problems derived from the use of these insecticides, as well as their persistence in the environment, led most of the countries to legislate environmental toxicology and human health. Starting in the 1970s, the use of DDT and other organochlorines began to be prohibited, and restrictions were imposed on other families of insecticides (Potter, 2011).

Pyrethroid insecticides have extensively occupied the market for urban pest control insects for the past 55 years (Zaim and Guillet, 2002). The World Health Organization recommends the use of pyrethroids for the treatment of materials and environments for the control of mosquitoes of medical importance (World Health Organization, 2005). The success of pyrethroids is related to their higher toxicity compared to the original pyrethrins, and to their better residual effect and lower photolability than plant extracts (Elliott et al., 1978; Zerba, 1988). Some compounds are very effective and cause rapid overturning, that is, a state of incoordination and locomotor instability that, depending on the dose, will lead to paralysis and eventually death. Furthermore, pyrethroids can have a repellent effect on insects, or antifeedant effect (Sfara et al., 2006; Romero et al., 2009b).

Currently, bed bug populations have been restored and are spreading globally (Romero et al., 2007). Numerous investigations have reported an increased number, intensity, and distribution of bed bug infestations in Africa (Gbakima et al., 2002), Europe (Masetti and Bruschi, 2007; Kilpinen et al., 2008; Fuentes et al., 2010; Levy-Bencheton et al., 2010), United States (Krueger, 2000; Anderson and Leffler, 2008), Canada (Hwang et al., 2005), Argentina (Cáceres et al., 2019), Australia (Doggett and Russell, 2008) and Southeast Asia (Lee et al., 2008; Suwannayod et al., 2010).

The first reports of bed bugs reemergence began in the mid-1990s and the number of infestations started to increase in several countries. For instance, United Kingdom pest control companies reported an increase in bed bug infestations at least to 100% in only 3 years (Koganemaru and Miller, 2013). Similarly, Doggett and Russell (2008) surveyed over 120 pest control professionals in Australia and recorded a 4500% increase in bed bug infestations between 1999 and 2006.

Many factors are involved in the re-emergence of this pest: the increase in tourism travel and commercial exchange (Potter, 2005), the furniture recycling, the lack of surveillance actions, and the insufficient variety of insecticides available (Koganemaru and Miller, 2013). In addition to the factors mentioned, resistance to insecticides is considered one of the main causes of the worldwide resurgence of bed bugs (Doggett and Russell, 2008; Romero et al., 2007).

Insecticide resistance is a common trait in urban insect pests and with medical relevance (Scott et al., 1990; Vassena et al., 2003; Picollo et al., 2005; Roca Acevedo et al., 2009; Knox et al., 2014; Koo et al., 2014). According to the Insecticide Resistance Action Committee (IRAC), resistance to insecticides consists in the inheritable change in the susceptibility of an insect population, which manifests itself with the repeated failure of an insecticide product to produce the expected effect when applied according to the label recommendations for the insect target (IRAC, 2018).

Resistance is developed by the irrational use of an insecticide on the pest species. In this way, the artificial selection pressure exerted by the chemical treatment will produce the death of the susceptible individuals and the survival of the resistant ones, and consequently, the evolution towards populations resistant to the insecticide. In addition to selection pressure, inheritance and gene frequency are intrinsic factors that strongly influence the evolution of resistance (Brogdon and McAllister, 1998).

A major concern with this situation is the lack of insecticides with different modes of action in order to switch among active ingredients that could be applied and to allow rational insecticide resistance management (IRM). Currently, neurotoxic insecticides such as pyrethroids and neonicotinoids are the only available for urban pest control and recommended for use against bed bugs are mainly the (EPA, 2019a).

However, the loss of efficacy of pyrethroids often leads to the use of insecticides that are prohibited or with a recommendation for limited use. For each of these groups, some degree of resistance has been demonstrated in bed bugs, which could suggest not only the illegal use of insecticides but also the presence of bed bugs populations with multiple resistance, that is, they possess more of a resistance mechanism that allows surviving the effect of more than one group of these insecticides (Adelman et al., 2011; Zhu et al., 2013; Gordon et al., 2014; Benoit et al., 2016; Romero and Anderson, 2016).

Many bed bug populations possess point mutations in genes that encode voltage-dependent sodium ion channels, that is, the target site of DDT and pyrethroids. Knockdown resistance (*kdr*), as this resistance mechanism is known, usually results from a replacement or exchange of the amino acid leucine by histidine, serine, or phenylalanine in the S6 hydrophobic segment in domain II of the protein (Williamson et al., 1996; Martínez-Torres et al., 1998). These mutations cause pyrethroids to lose their effectiveness in acting on the target site. V419L and L925I mutations in the voltage-dependent sodium ion channel α subunit have been described as being responsible for pyrethroid resistance in bed bugs (Yoon et al., 2008; Zhu et al., 2010).

Furthermore, many resistant *C. lectularius* populations have been shown to have an increased ability to detoxify insecticides (Romero et al., 2009a; Mamidala et al., 2011; Zhu et al., 2012; Romero and Anderson, 2016; Cáceres et al., 2019). This mechanism may be due to gene overexpression of one or more of the main classes of detoxifying enzymes: cytochrome P450 monooxygenases (OFM), carboxylesterases (EST) and glutathione S-transferases (GST). In particular, the overexpression of several P450 genes has been related to resistance to deltamethrin in several populations of bed bugs (Zhu et al., 2013). Pyrethroid detoxification activity has also been observed by esterases at the molecular level (Adelman et al., 2011) and through the use of synergists (Cáceres et al., 2019).

Insect cuticle modification is a unique and efficient mode of insecticide resistance (Lilly et al., 2016), that can operate by the reduction in the penetration of the insecticide and its passage to the hemolymph. This may be due, in part, to the production of detoxifying enzymes in epidermal cells (Mamidala et al., 2012; Zhu et al., 2013; Benoit et al., 2016) or to the over-expression of CPR genes (cuticular proteins) in resistant bed bugs (Koganemaru et al., 2013). In turn, as evidence of the effect of reduced penetration, the susceptibility to the insecticide is greater when it is injected directly into the hemolymph, unlike application by topic (Adelman et al., 2011; Koganemaru et al., 2013).

Also, there is a known behavioral resistance mechanism in several insect species (Wang et al., 2004; Buczkowski et al., 2005; Rust and Saran, 2006; Chareonviriyaphap et al., 2013), but less studied in bed bugs. At the beginning of an insecticide poisoning, the symptoms that manifest are hyperactivity, irritability or repellency (Alzogaray and Zerba, 1997). Instead, resistant individuals can

perform behaviors that reduce exposure to the toxic compound, or that allow it to survive in an environment that is harmful to most insects (Haynes, 1988; Chareonviriyaphap et al., 2013).

In particular, it has been observed that resistant bed bugs were able to avoid pyrethroid-treated areas when a heat source, as an attractive host stimulus, was present (Romero et al., 2009b). Additionally, bed bugs can remain in shelters impregnated with insecticides, and neither aggregation behavior nor survival was affected by the residual action of the insecticide (Moore and Miller, 2009; Romero et al., 2009b). Although these types of responses are considered innate behaviors, the underlying genetic basis requires much more in-depth analysis in bed bugs.

Traditional and new strategies for bed bugs control

The infestations of *C. lectularius* and *C. hemipterus* are usually achieved through a set of strategies that include non-chemical (physical) and chemical (insecticides) methods. Nowadays, a variety of non-chemical methods are available such as aspiration, heat, passive monitoring traps (sticky traps) and exclusion, and their effectiveness will depend on the magnitude of infestation (Potter, 2011). However, visual inspection made by pest control operators is an important first step to take before the application of any control treatment. Many pest control companies are providing trained dogs, which are capable to detect (smelling bed bug odors) the bed bugs refugees in rooms or furniture. Also, the use of monitoring devices can aid in early detection and could be more effective than visual inspections. In the early stages of an infestation, mechanical removal through aspiration or the heat and steam treatments could be useful for controlling or even killing bed bugs (Koganemaru and Miller, 2013).

However, insecticides are central for any control pest service aimed to reduce bed bug infestations (Potter, 2011). Currently, insecticides with different modes of action are used to bed bugs control (Davies et al., 2012; Potter and Haynes, 2014). However, pyrethroid insecticides applied alone or in combination with neonicotinoids, are widely used by pest control professionals in the United States. Other insecticides, such as pyrroles, desiccant powders, and insect growth regulators are used but to a lesser extent than pyrethroids (Romero et al., 2010b; Goodman et al., 2012; Potter et al., 2015).

The widespread of insecticide-resistant bed bugs has renewed interest in developing more effective control methods. In particular, given that bed bugs can develop high resistance to pyrethroids and also could display multiple resistance mechanisms that making ineffective almost any known insecticide. The addition of enzymatic inhibitors, e.g., piperonyl butoxide (PBO), in pyrethroids formulations can be a good option to improve pyrethroid toxicity (Cáceres et al., 2019). However, the PBO is only effective against resistant bed bugs that possess metabolic resistance (with P450 enzymes as the main responsible for the detoxification of insecticides) (Romero et al., 2009a).

The presence of mutations at the target site can be counteracted by the selection of insecticides with different modes of action. For instance, chlorfenapyr [4-bromo-2- (4-chlorophenyl) -1-ethoxymethyl-5-trifluoromethyl-1H-pyrrole-3-carbonitrile] (Pyrroles—Group 13: decoupling of oxidative phosphorylation) is considered an alternative, although its effect is slow-acting (Romero et al., 2010b). There are a large number of insect growth regulators (IGR) but their efficacy in the control of bed bugs is poorly studied (Goodman et al., 2012; Koganemaru and Miller, 2013). For instance, there are some evidence that the continuous exposure to lufenuron [1- [2, 5-dichloro-4- (1, 1, 2, 3, 3, 3-hexafluoropropoxy) phenyl]—3- (2, 6-difluorobenzoyl) urea]—Benzoylurea, Group 15: inhibitors of chitin synthesis caused significant reduction in experimental colonies of bed bugs susceptible and resistant to pyrethroids (Garramuño, 2018). This result demonstrates the potential efficacy of this IGR in controlling bed bugs, while also being a suitable alternative for managing pyrethroid resistance.

Although neurotoxic insecticides will continue to play an important role in bed bug control, the future will also depend on the development of new insecticide formulations, safe for human health and environmentally friendly. Nowadays, formulations with organic solvents or the addition of surfactants (and cosurfactants) are needed to improve the power and residual effect of the active ingredient (Pratap and Bhowmick, 2008). Also the formulation of insecticides based on emulsions allowed to reduce the use of organic solvents, but at the same time, they require the incorporation of greater amounts of surfactants and other additives to improve their properties. All these methods have allowed more efficient use of insecticides but have not been able to solve the problem caused by their discharge into the environment, the effects on non-target organisms, or reduce production/application costs (Bhagat et al., 2013).

On the other hand, the incorporation of alternatives to insecticides should be incorporated in programs for bed bugs integrated pest management (IPM). Control strategies based on modifying the behavior of blood-sucking insects, such as repellents and attractants, are suitable approaches to overcome insecticide resistance and provide protection to people (Foster and Harris, 1997).

The use of repellents is one of the best known and most effective methods for the control and prevention of insects. As a general definition, a repellent is a chemical compound that causes insects to move away from the emitting odor source (White and Moore, 2015). N, N-diethyl-m-toluamide (DEET) is the most widely used insect repellent (Moore and Debboun, 2007) because of its great efficacy, a broad spectrum of use and low toxicity in humans (EPA, 2019b). However, most of the repellency studies of DEET and other natural and synthetic compounds have been carried out on mosquitoes (Swale et al., 2014; de Souza et al., 2019), ticks (Jaenson et al., 2005), or triatomines (Zermoglio et al., 2015; Reynoso et al., 2017). In comparison with these insect pests, the bed bug repellence was poorly studied (Kumar et al., 1995; Wang et al., 2013). For instance, the repellent effect of DEPA (N, N-diethylphenylacetamide) on *C. hemipterus* was only significant at very high concentrations, compared to the effective dose in other insect species (Kumar et al., 1995). Also, the starvation period can promote repellence by DEET in bed bugs. In contrast, this

behavior was different in those resistant bed bugs, which were more tolerant to different concentrations of DEET (Vassena et al., 2018).

Chemical communication plays an important and essential role in insect survival (Pickett et al., 1997). Semiochemicals are natural compounds used by insects as specific chemical signals that modify behavior or certain physiological processes (Wyatt, 2009). Insects use semiochemicals to host search or for mating, to avoid competition or natural enemies (Reisenman et al., 2016). These natural compounds have high specificity and are probably safer, both of which are advantages compared to insecticides and synthetic compounds used for pest control. These properties make them promising tools for the integrated management of numerous pest insect species.

A wide range of semiochemicals (volatiles and non-volatiles) are involved in numerous insect behaviors. The chemical composition of alarm and aggregation pheromones has been already identified in bed bugs (Siljander et al., 2007; Gries et al., 2015), as well as the importance of non-volatile feces compounds in aggregation behavior (Olson et al., 2017). In contrast, there are components of the insect cuticle that not only have a primary role in protecting the internal conditions and regulating dehydration but also can be a source of chemical clues that insects use for recognition in different life contexts (among social insect castes, sexes, parents and offspring). Studies done on bed bugs have not yet been able to elucidate the effects of cuticular components on behavior (Pfiester et al., 2008; Domingue et al., 2010), and the chemical composition has not been exhaustively studied either (Feldlaufer and Blomquist, 2011).

Semiochemicals have great potential for use in bed bug management, for example, bed bug semiochemicals could be incorporated in bait traps for both control treatment and monitoring (Weeks et al., 2011). Furthermore, the use of these traps after the application of insecticides would also make it possible to determine the success of the control effort, or the need to continue treating the pest (Koganemaru and Miller, 2013).

Etymology

Name: German: Floh; English: flea; origin in the old German term: fliehan = flee; French: puce; Spanish: pulga; Italian: pulce; Chinese: 跳蚤; Russian: Блошинный.

Morphology, biology and ecology

The approximately 2500 species of fleas (Tables 1–3; Figs. 1–3 and 7–9) belong to the group of the insects, which got their Latin group name (*insectus* = carved in) due to the existence of deep incisions between head and breast and between breast and abdomen. About 94% of them suck blood on mammals, the remaining ones on birds. All these fleas are characterized by the facts that they are wingless, but possess six long, strong legs, which allow jumps of up to 35 cm in length to escape enemies such as birds or to reach preys (warm blooded animals), where they may suck blood, which they need obligatorily to proceed growth and reproduction.

Their laterally depressed body is principally segmented in head, breast, and abdomen, whereby the rather tiny head and the breast are not clearly separated. The 6 ft are each equipped with a pair of claws, which allow a firm hold at the hair of their hosts (animals, humans) (Fig. 4A and B) and on the carpet (Fig. 5).

Their head capsule is rather small and dorsally equipped by a pair of segmented antennae, which might be redrawn into a deepening of the cuticular head capsule (Figs. 1, 3, 4A and B, 5), when moving in the fur of host animals or on the body of humans respectively in their clothes. At each of both lateral sides of the head one rather primitive eye (ommatidium) is located consisting of four crystal cone cells and two pairs of main and covering cells. At the ventral side of the head the mouthparts of the sucking type are present enabling the flea to penetrate with their mouthparts into the skin of their hosts and to ingest their blood, which they keep fluid by injection of saliva containing anticoagulation components.

The terminal end of the rather large abdomen is equipped with a so-called pygidial-plate, which contains numerous sense hair, which are called trichobothria and which apparently recognize air movements and odors of potential hosts, so that flea can reach them by help of their enormous jumps of up to 30 cm or become able to flee from enemies.

The individual holometabolous life cycle of fleas comprises the following stages: eggs, three larval stages, a pupa and the male and female stages. Fleas reach a life period of a maximum of about 1½ years. The copulation often takes place on a host, whereupon, for about 3–6 weeks, the female daily lays 10–25 eggs that drop from the host's surface to the ground. The cat flea for example deposits about 800–1000 eggs like this, while the human flea produces in mean only 450 eggs. After ~5 days (temperature dependent), the eyeless larva hatches from the egg, which is also called "wireworm" because of its bristled appearance. These stages mainly feed on detritus. However, they also need proteins for their development. They obtain them by ingesting portions of dead adults or by ingesting fecal drops, which contain remnants of blood being constantly excreted by the adult fleas.

After about 2–3 weeks and two molts, the larvae spin themselves a silky cocoon by help of their salivary glands. Within about 3 more days, the larva develops into a pupa and stays—depending on the microclimate—in this immobile condition for about 1–2 weeks. The hatching from the pupal cocoon is mostly triggered by an external stimulus, e.g., vibrations indicating the arrival of a host. If this stimulus is omitted—because no host visits the flea populated lair—the adult flea can stay for months in this pupal cocoon, apparently with a reduced metabolism. The arrival of the first host then provokes a sudden mass exodus of the adult fleas from all present pupae. This occurs identically in the cases of a resettlement of an old nest by birds, of a kennel by dogs or of an apartment by humans. Because 99% of a flea population is located on the ground, control measures have also to be directed against these stages. This can be done by help of sprays containing chemical compounds, which prevent the molt of the larval stages and thus stop the occurrence of new replication-competent adults. If at the same time adult insects are controlled with insecticides (today: pyrethrum or pyrethroid = original or synthesized agents from chrysanthemum), even massive flea infestations can be eliminated from dwellings and animal lair.

The most important flea species parasitizing on humans and its pets are listed in [Table 1](#). They are not only of importance because of their bloodsucking activity, but some of them serve (by contaminated mouthparts) as mechanical vectors of pathogens or as intermediate host of parasites.

More than 2000 species of fleas have been described worldwide, of which about 80 are found in Central Europe. However, only 5–10 species are really very important with respect to a potential vectorship of agents of diseases of humans and animals ([Table 1](#)). The species diagnosis of fleas is rather difficult and cannot be done just by consideration of the host, where the flea had been detected.

The last larval stage ([Figs. 1, 2, and 5](#)) of the fleas is transformed into the pupal stage wherein the adult female or male flea is developed. The whitish eggs are excreted in different series ([Fig. 5](#)). The females of *Pulex irritans* produce in total up to 450 eggs during their life, while the cat flea (*Ctenocephalides felis*) can lay up to 1000 eggs, which are excreted in daily packages of about 25. Thus, a single, fertilized female flea may start a real flea invasion in a dwelling.

The larval development takes about 14 days (at 18–29 °C and at 70–90% humidity) in the case of the so-called human sand flea *Tunga penetrans*. In the case of chicken fleas (*Ceratophyllus gallinae*), dog fleas (*Ctenocephalides canis*) and cat fleas (*C. felis*), this development is somewhat shorter. However, in the literature also periods have been reported ranging from 16 to 460 days. The larval development occurs mainly inside/on the resting sites of their hosts. Thus, to verify the existence of fleas in a dwelling it is needed to start the search for the whitish, worm-like maggots. The so-called human flea *Pulex irritans* proceeds its development in dusts close to human beds and they can only hardly be seen by naked eye, since they are very often covered by dust. These flea larvae do not suck blood since their chewing mouthparts are unable to cut the skin of humans or animals. However, on the other hand, adult fleas of both sexes have biting-sucking mouthparts (Figs. 4B, 6, and 8A), which can enter the skin of humans and animals. By their help they suck blood several times per day, whereby they inject compounds, which keep the blood fluid, but which also

cause allergic skin reactions and itching. Thereby they ingest in a hasty manner more amounts of blood than they can use. Thus, they excrete within their feces portions of blood, which then serve as food for their larvae. The last one of three larval stages excrete a fluid, which hardens and thus forms the pupal cover. Therein the female or male adult flea is formed within 7–10 days. The whole development from egg to an adult flea is temperature dependent, e.g., in moderate European temperatures it takes about 4–6 weeks, but it needs less time in warm regions or in very warm indoor rooms in colder regions of earth. Human fleas and related species need at least a minimum of humidity, so that the in general rather dry human dwellings are poor biotopes for their progeny.

Fig. 4 (A) Light micrograph and (B) scanning electron micrograph of *Pulex irritans*.

Fig. 5 Scanning electron micrograph of stages of the cat flea on the floor. Above: adult flea; left below: egg with a hatching larva; right below: larva 2 (= "wireworm").

Fig. 6 Light micrograph of a male flea of *Ceratophyllus* sp. (main hosts: poultry).

The cat flea *C. felis* (Table. 1; Figs. 1 and 2; Vobis et al., 2003), however, is not very dependent on significant ranges of temperature and humidity and thus is now much more common in human dwellings than *P. irritans* or other flea species. This flea, which attacks besides cats also dogs and humans, represents now 80% of the fleas occurring in European human dwellings. Inside its pupal cover (cocoon), the ready to hatch adult flea may starve for long (up to 1 year), since it waits for signals like soil shaking, which announce the arrival of a potential host. This is important to know for people who move into an apartment, which was the home of dog or cat owners and stood empty for a longer period. The newcomers may become attacked by large numbers of suddenly hatching fleas or others, which had starved for long. The same behavior is described from bird fleas, which rest inside their pupa cover until another bird enters the nest or they attack when humans start cleaning bird cages, etc. The adult fleas leave dead

hosts as soon as the body cools down. This is important in the transmission of the agent of plague (the bacterium *Yersinia pestis*). If infected rats die, the fleas leave them and attack humans, whereby they transmit eventually present plague bacteria within their saliva during blood sucking. The transmission of agents of this disease into human hosts is proceeded by regurgitation of blood containing the bacteria. There are the following steps:

- (1) A flea ingests the bacteria at an infected rat or a human being.
- (2) The flea changes the host and attacks after a while or immediately another human being.
- (3) The flea starts to suck hastily human blood, which is mixed in its prestomach with the remnants of a meal of rat or human blood containing the infectious bacteria.
- (4) Then the non-stretchable anterior portion of the flea’s gut becomes overfilled and therefore the flea vomits. Thereby it regurgitates the whole blood mixture containing the bacteria into the wound of the human skin.
- (5) Then these bacteria in general start their propagation inside the human blood and thereby induce severe symptoms of disease, which may lead to death. In former times this disease was called Black Death due to the appearance of numerous black spots on the skin of dying persons.

Especially the tropical rat flea (*Xenopsylla cheopis*) (Table 1; Fig. 7) is a very important vector of the agents of plague, since it is worldwide especially high common on rats in human slums. Thus, outbreaks of plague occur even today especially in many regions of India, East Africa and even the United States (Abdullah et al., 2019; Beaucournu et al., 2012; Clark et al., 2018; Frank et al., 2013; Gilles et al., 2009; Grüntzig and Mehlhorn, 2010; Gyimesi et al., 2007; Kreppel et al., 2016; Lawrence et al., 2015, 2019; Márquez, 2015; Mead, 2018; Mehlhorn, 2012a,b; Mehlhorn, 2016a,b; Nagy et al., 2007; Oteo et al., 2014; Peus, 1938; Rzotkiewicz et al., 2015; Sanchez and Gomez, 2012; Sekeyová et al., 2012; Vobis et al., 2004; Zurita et al., 2019; Zhao et al., 2018).

Bite reactions

Fleas are easily disturbed during blood sucking. Then they stop it and start a new approach at a different site of the host body. Thus, there can be found real rows of bites along a human skin (Fig. 10). The injected saliva, which keeps the host's blood fluid, initiates intense itching, which is several times repeated, if a host reacts by scratching at a bite site. However, reactions on bites may range from not occurring or not noted to extremely intense reaction depending on the allergic status of a host (Fig. 11)—but in any way itching is nasty and may remain for several days.

Transmission of agents of disease

The history of mankind is full of examples, where fleas had influenced the fate of single persons but also that of whole nations, since fleas are common vectors of important agents of diseases.

Plague: This disease, which has killed millions of humans in times before the invention of antibiotics, is due to infections with the bacterium *Yersinia (Pasteurella) pestis*. This non-flagellated, gram-negative, stab-like bacterium, which was detected and described in the year 1896 in Hong Kong by co-workers of Robert Koch and Louis Pasteur: Shibasaburo Kitasato (1853–1931) and Alexandre Yersin (1863–1943) during an epidemic in Hong Kong, is transmitted by fleas during regurgitation of bacteria-containing blood.

Fig. 10 Flea bite reactions of humans. Fleas bite often in rows after having been disturbed during sucking.

Fig. 11 Skin reaction due to flea bite allergy.

These bacteria are equipped with a capsule of proteins, which act antigenic and block phagocytosis. They reach within blood and lymph the lymph fluid nodes which during infections increase their size extremely within 3–5 days after the flea bite and appear in a hemorrhagic red color. These swollen regions occur in about 90% of all infections and were called bubones. Via blood transportation the agents of disease then may enter the lung, where they reproduce themselves enormously so that during coughing slime masses with millions of bacteria are expectorated and may infect other persons. This phase—called lung pest (plague)—leads to death without treatment. Thus, it is understandable that in pre-antibiotic times plague has extremely reduced the human populations in many countries around the world. For example, after the European so-called 30-Year Wars (1618–48) as many people had been killed that only 5 million humans survived in the region between Breslau and Paris (over more than 1200 km). Plague is still today present in India, Africa and North America and starts local outbreaks. For example, in the year 1994 there was a plague breakout in India close to a monastery (where “holy” rats had been kept) leading to thousands of human cases. This outbreak made big problems, since the urgently needed supply with antibiotic was too slow. Treatment of plague is actually done by application of antibiotics such as tetracyclines or aminoglycosides.

Murine spotted fever: The agents of this fever and related types (*Rickettsia typhi* = *R. mooseri*) are common in rats in many tropical and subtropical regions. Today treatment is done by application of tetracyclines and chloramphenicol. However, extremely important and highly needed is the intense control of the plague hosts such as rats and fleas, which live often in close surroundings of human houses.

Erysipeloid: This disease is often found in Russia and is induced by the bacterium *Erysipelothrix rhusiopathiae* which leads to severe skin damages in many animals and immune-compromised humans.

Viruses: The groups of Mehlhorn and Mencke (Germany) proved by transmission experiments that flea may transmit a broad spectrum of viruses (e.g., Caliciviruses), which are stable enough to survive for a while in the stomach of fleas (Mencke et al., 2009; Vobis et al., 2003). These agents were found as well as inside flea saliva as in flea feces, where they remained infectious for up to 60 days (!) (Beck and Prosl, 2010; Bosio et al., 2014; Cagnon et al., 2019; Contreras et al., 2018; Hajipour et al., 2014; Hornok et al., 2014; Kapoor and Elston, 2012; Klimpel et al., 2005; Kumsa et al., 2014; Mencke et al., 2003; Miarinjara et al., 2017; Miller et al.,

2019, 2020; Raking, 2003; Ranaivozanany et al., 2020; Ramasindrazana et al., 2017; Robert Koch Institute (RKI), 2020; RKI Berlin, 2020; RKI STAKOB, 2017; Schmidt-Chanasit, 2014; Simona et al., 1998).

Transmission experiments with feline leukemia virus via fleas

As described in the paper of Vobis et al. (2003), the following results were obtained in an artificial feeding system (Artificial dog from FleaData Inc., Freeville, United States), where fleas have the chance to ingest blood from small blood containers via membranes. The whole system was adjusted to keep the blood temperature at 37 °C. In the first feeding, an initial population of 110 fleas was infected with feline leukemia virus (FeLV) through feeding for 24 h with 2 mL blood from a viremic cat (Table 4). To verify the successful uptake of viruses, 10 fleas and whole feces of this initial population were tested for FeLV RNA. The viral RNA could be detected in both samples, fleas and feces. The FeLV was incorporated by the fleas via blood feeding and was excreted with the feces. The remaining 100 infected fleas were subsequently divided in two populations of 50, where population 1 was fed for 24 h and population 2 for 5 h with 300 µ uninfected blood from a healthy cat. After the defined time, 10 fleas and feces of each population were tested for FeLV. Viral RNA could be detected in fleas of both populations as well as in their feces. FeLV RNA was detectable for 5 and 24 h, respectively, after uptake by the flea and feeding with uninfected blood. To investigate whether transmission of FeLV occurred, the remaining blood from transfection 1 and 2 was examined. Viral RNA could be detected in both samples of the previously uninfected blood from a clinically healthy cat. This shows that the cat flea *C. felis* can function as a vector for feline leukemia virus RNA in this in vitro system of an artificial dog. Viral RNA was detectable in the fleas and their feces for up to 24 h. In addition, the fleas successfully transmitted FeLV RNA directly from an infected blood sample to an uninfected one.

In a third feeding study, the same fleas, their feces and blood samples were examined for FeLV. After this third feeding, viral RNA could not be detected neither in the fleas, their feces, nor in blood samples. FeLV RNA was detectable in the fleas up to 24 h after feeding. During this time, fleas also excreted viral RNA within their feces. In addition, the fleas can transmit FeLV RNA directly from one blood sample to another and functioned therefore as a vector of the virus.

In quantitation measurements (Vobis et al., 2005a,b) using the same artificial dog system as in the first series (Vobis et al., 2003), it was shown that around 70% of the ingested virus stages are able to withstand passage through the intestine with at least an intact nucleocapsid and is excreted and spread into the flea feces and thus into the surroundings. When comparing the degradation rates of the FeLV in cell culture supernatant, the nucleocapsid seems even more stable in the feces. About 55% of the initial amount of the viruses could still be detected after 15 days when keeping the fleas at room temperature. Lower temperatures led to even higher survival rates.

These experiments showed that the viruses were transmitted by sucking (and apparent regurgitation) and that they were definitively surviving for days within the feces thus endangering humans when reaching their dwellings.

Transmission experiments with feline calicivirus

To find out whether flea feces do not only contain the probably unchanged viruses, in vivo experiments were done using the feline calicivirus (FCV) (Mencke et al., 2009). Fleas were inoculated with the viruses in the artificial dog system containing bovine blood free of FCV antibodies but being spiked with FCV to give a final titer of 10^6 TDC₅₀/mL. The flea feces were collected daily for 10 days and incubated at room temperature. When using Crandell-Rees feline kidney (CRFK) cells, it was shown that the FCV apparently remained infectious in feces for 8 days. When exposing four specific pathogen-free (SPF) kittens oro-nasally to the virus-containing feces, all four were successfully infected (two kittens showed clinical symptoms). Four additional SPF kittens were exposed to fleas that had been fed with FCV-spiked bovine blood. One of these kittens was proven to be definitely infected in this way when testing virus isolation from pharyngeal swabs.

This series of experiments clearly showed that fleas may play an important role in the transmission of viruses under certain conditions, either during the blood meal and/or in the case that hosts get in contact with the flea feces. The only, but very important condition is that the transmitted virus is rather stable. However, there are many viruses known to fulfill these conditions, so that viruses transmitted by fleas may introduce emerging diseases under these conditions.

Table 4 Transmission experiments using the feline leukemia virus.

Prophylaxis and flea elimination

In case of temporarily keeping fleas for experiments, use first insecticides to clean the vessels (e.g., with Alugan®-Spray or pyrethrum spray, e.g., Axis®Natur, or spraying with INS 15 or CBM 8®). Repetition of the treatment should be done every 10–12 days and regular cleaning of the sleeping place (carton with a lateral opening and a heat keeping bottom consisting of wood or thick cardboard).

To avoid transmission of agents of disease by flea bites or flea feces, the pet animals should be protected by insecticidal collars and pour-on preparations containing insecticides (e.g., Advantix®, Bayer, Germany). The latter, however, might not act fully against flea larvae, which, however, may be killed by e.g., MiteStop®, Alphabiocare, Germany, an extract of neem seeds, which dries up the surface layer and thus kills the larvae (Gopinath et al., 2018; Rust, 2016, 2017).

Introduction

There exist two groups of lice, which attack humans: bloodsucking (Anoplura) and chewing lice (Mallophaga). The bloodsucking lice (German: *Läuse*; French: *pou*; Spanish: *piojo*; Italian: *pidocchio*) as well as the chewing lice (mallophages) belong to the animal phylum of the Arthropoda (Greek: *arthron* = segment; *pous/podos* = foot). Inside this phylum the lice are placed into the group of Insecta respectively Hexapoda, which are characterized by six legs (Greek = *hexapoda*) and by the division of the body into head, thorax and abdomen, being visibly separated from each other by more or less deep incisions. Among the insects the lice belong to the systematic order Anoplura (Greek: *anoplos* = unarmed, *ura* = tail). The lice of humans, although being much older than the recent *Homo sapiens* (Figs. 1 and 2; Aspöck and Walochnik, 2007) have coevolved with the human beings over the last 5–6 million years. Thus, they are today exclusively found on the bodies of the recent 7 billion “winners of the evolution”: *Homo sapiens*.

These exclusively human lice belong to two genera:

- *Pediculus humanus capitis* (head louse; Latin: *pediculus* = little foot; *humanus* = human; *caput* = head); measuring in length: ♀ 2.6–4 mm; ♂ 2.4–2.9 mm (Fig. 2).
- *Pediculus humanus corporis* (body louse; Latin: *corps*, *corporis* = body); measuring in length: ♀ 3–4.8 mm; ♂ 2.7–3.8 mm (Fig. 3).
- *Phthirus pubis* (pubic louse; Latin: *phthir* = louse; *pubes* = region around primary sexual organs); measuring in length: ♀, ♂ 1.3–1.6 mm (Fig. 4).

Some authors claim that the races of the genus *Pediculus* are already separate species and thus they should be named *Pediculus capitis* and *Pediculus humanus*. However, in cross-breeding experiments it has been shown that members of both races may produce a fertile progeny. However, such a “mixture” apparently does not occur on the human body, since both races prefer the different body temperatures that occur on the surface of the scalp and the rest of the body respectively.

Today lice infestations are one of the most common human infections in the world—especially in kindergarten and in school-children aged between 3 and 15 years. It is estimated that even in countries with high hygienic standards, such as the United States of America, high infestation rates exist (about 6–12 millions of kids just in the United States), that result in several million lost school

Fig. 1 History of the lice of humans (Aspöck and Walochnik 2007). Note that lice attacking humans branched off around 5–7 million years ago (Kopflaus = head louse; Kleiderlaus = body louse; Filzlaus = pubic louse).

days and treatment costs of more than \$5 billion per year. Similar costs must surely exist worldwide in all countries where there is medication available for purchase. Thus it is a reasonable goal to establish significant, safe, healthy and low budget eradication methods for lice control in a world of growing resistance (Abdel-Ghaffar et al., 2010a,b, 2012; Burgess, 2004; Gur and Schneeweiss, 2009; Lebwahl and Levitt, 2007; Mehlhorn, 2016a,b,c; Mehlhorn and Mehlhorn, 2014; Meinking et al., 1986; Mumcuoglu, 1999; Amanzougaghene et al., 2016; Arnaud et al., 2016; Asala and Mbajiorgu, 1996; Bartlow et al., 2016; Boutellis et al., 2014; Boyd et al., 2017; Bressa et al., 2015; Coulaud et al., 2015; Dos Santos et al., 2011; Gustafsson et al., 2015; Gustafsson et al., 2019; Kagira et al., 2013; Leitinger and Richter, 2018; Mehlhorn, 2012; Mey, 1988; Smith et al., 2013; Valim and Cicchino, 2015; Veracz and Raoult, 2012; Wang et al., 2014).

Head lice

Morphology of head lice (*Pediculus humanus capitis*)

Among the general characteristics of head lice, the following features can be noted:

- Their body, covered by a stiff yellowish-brown appearing cuticle, is visibly divided into three regions: head, thorax and abdomen. Only in the abdomen are the different segments clearly visible, while those of the head (caput) and thorax are more or less fused (Fig. 2A and B).
- The head has a "pig-like" snout, within which the two channels of the blood sucking mouthparts are retracted.
- The head bears two rather large, somewhat protruding eyes, which are clearly pigmented.
- Furthermore, the head has two motile antennae (tentacles) bearing fine-smelling sensillae; each of these antennae consists of five segments (Fig. 2).
- The breast comprises three segments being closely melted. At the dorsal side, there appears a central depression, which is due to the fact that at its inner side strong muscles are affixed. The dorsal side of the lice does not possess wings at any stage of the development (Fig. 2).
- The thorax is equipped on each side with one spiracle = stigma (which represents the opening of the tracheal = respiratory system).
- Ventrally at the breast three pairs of feet are attached, echoing the former existence of three clearly separated thorax segments (pro-, meso- and metathorax).
- Each of the six feet consists of five typical segments (coxa, trochanter, femur, tibia and tarsus). All terminal tarsus segments are transformed into giant claws, which can clutch different single hairs. This system helps lice to avoid to become separated from their hosts, an important feature, since head lice live exclusively on humans. In exceptional cases when fallen down from a host, they need to find a new host within a short period of 5–6 h, otherwise they will die. Therefore, lice try to stay on a host.
- The hind body (abdomen) of the head lice louse is composed of 10 true segments. The first two are greatly reduced and do not bear the paired lateral openings (spiracle, stigma) of the respiration system, which are clearly visible on the lateral sides of the segments 3–8. Segments 9 and 10.
- The position of the opening of the sexual organs differs in both sexes. While the male opening can be found at the back line of the ninth segment, the female system opens one segment earlier (at the posterior end of the eighth segment).

- The copulation system of the male leads to a pointed aspect of the terminal end of the male stage, while the females are characterized by a slight terminal bifurcation.
- The intestines of all blood-sucking head lice stages start with the apical, “pig-like” snout, within which an invagination (containing the two protruding channels of the blood sucking system) has its terminal end. The mouth is adjacent to the pharynx with its numerous muscles, thus forming a strong pumping system. The esophagus transfers the engorged blood into the stomach, which forms laterally two short blinded extensions (ventricula), which are directed anteriorly. The stomach is stretched to the posterior end of the 6th abdominal segment and is followed by a small-sized intestine forming an anterior loop. At its border to the terminal portion (hind gut, colon) the tubes of the excretory system (Malpighian tubules) enter the intestine. The anus finally opens at the end of the 8th segment, while segments 9 and 10 appear as a combined block.
- The inner ventral side of the stomach is lined by a system of supporting microorganisms (bacteria) forming a so-called mycetome, which is essential during the digestion of the food.
- The male sexual organs consist of two testes (each with two lobes), from where a “ductus seminalis” transfers the sperms to two sperm bladders with glands. Finally, the ends of these bladders are united and terminate in an injector, which may become protruded and injected into the female system.
- The female sexual system consists of two ovaries each with five lobes containing the produced eggs. After fertilization, the eggs are excreted via the two oviducts, which are lined with symbiotic microorganisms being transferred to the eggs. The oviducts fuse to create a single terminal portion, which does not form a “receptaculum seminis” (a sperm storage system), but is lined by two glands (each with three lobes) producing an adhesive material that eventually covers the eggs. The females are thus able to attach them firmly to the hair close to the scalp. Due to the lack of a sperm storage pocket (receptaculum seminis), lice copulate several times during their adult life span.

Life cycle of head lice

The life of a head louse as well as of other lice (Fig. 7) starts with the copulation between a male and female louse. After fertilization, whitish eggs about 0.5–0.8 mm long become glued to the basis of hair. Then it takes 6–9 days for the six-legged larvae (some authors call them nymphs) to hatch from the egg by blasting off the covering operculum which contains several typical semi-open aeropyles that allow the entrance of oxygen. The larvae suck blood at intervals of 2–4 h and thus grow rapidly. After three moltings (over larvae 2 and 3) the adult stage is reached within 8–11 days, so that the whole generation usually only takes 17–20 days. The developmental larval stages and both adults suck blood every 2–4 h. The females live as adults for about 20–25 days and lay 2–9 eggs per day, so that a total reproduction rate of 50–150 eggs per female is reached (Reichenow, 1946). In the beginning, just after placing the eggs at the base of the hair, the eggs (nits) are brownish. Since the hair grows about 0.2 mm per day, it takes weeks before the eggs (nits) become visible as brilliant white globes at the terminal ends of the hair (Figs. 5 and 6). By this time, the nits are long since empty and thus cannot be used as a means of ascertaining the existence of a living louse population on a head.

All stages of the lice (Fig. 7) need to avoid falling off a head and have thus developed giant claws. However, females—if fertilized—have a peculiar way of transferring living and fertile females to another host (e.g. propagation of an existing louse population). Immediately after a “good” blood meal the fertilized females run to the end of the hair driven by a behavioral adaptation called positive phototaxis. If this lurking female gets cold after a waiting time of about 1–2 h, it runs back to the scalp and starts feeding again. However, in the event of hair-to-hair contact between two people, while a female louse is lurking at the end of the hair, she may enter the new host and become the mother of a new population. If the adult females drop off a head and fail in finding a new host within the next 5–7 h, most of them will die by desiccation. Gallardo et al. (2009) proved that practically all males and 97% of the females died at a room temperature of 24 °C at a rather low room humidity. This is clearly different from the

Fig. 5 Light micrograph of three lice eggs being glued at a hair.

Fig. 6 Scanning electron micrograph of an egg of the head louse being glued at a hair. Note the openings at the cover (operculum). The developing larva is inside protected from drying up by a fine membrane.

Fig. 7 Diagrammatic representation of the life cycle stages of the Anoplura and Mallophaga.

survival chances of body lice, which can survive starving periods of up to 10 days on the floor, if there are rather low temperatures in a room (0–6 °C). Heating the room significantly lowers the survival time of body lice in a room. At room temperatures of more than 20 °C, they only survive for 2–4 days (Reichenow, 1946).

Thus, there are completely different needs, when outbreaks of head or body lice occur within one room. In the case of head lice there are practically no further precautions needed due to their short survival time and the extreme rarity of them voluntarily leaving the head of a victim in the direction of the floor, etc. In the case of body lice, however, rooms have to be heated for 5 days at temperatures close to 30 °C or must be left empty for at least 10 days until the danger of being attacked by body lice from the floor or beds has passed.

Epidemiology of head lice infestations

Human head lice have co-evolved with mankind and are thus cosmopolitan parasites, found in all areas of the world and in all socio-economic classes. Contrary to popular belief, pediculosis (infestation of lice) occurs in anyone regardless of ethnic origin, economic status, family background, religion or personal habits. The only exception is that longer hair supports transmission, since this leads to higher numbers of hair-to-hair contacts with possibly infested persons. This explains why girls are generally more often infected than boys. In general, and in practically all countries, the highest prevalence rates of pediculosis are found in pre-school and elementary-school children (3–10–15 years). There are reports of prevalence rates of 5% up to 56% in different countries (Al-Shawa 2006; Bauer et al., 2009; Buczek et al., 2004; Downs et al., 1999; Falagas et al., 2008; Govere et al., 2003; Hemingway et al., 1999; Heukelbach et al., 2005; Kokturk et al., 2003; Mumcuoglu et al., 2009; Speare and Büttner 1999; Toloza et al., 2009). The increasing rates of lice infestations worldwide follow certain seasonal fluctuations (Bauer et al., 2009), which depend on climate conditions and behavioral activities. Thus, Heukelbach et al. (2005) reported that in a slum in a semi-arid region of Brazil the prevalence of pediculosis varied considerably during the year. It was 44% in the raining season (when humidity is high and temperatures are rather low), but decreased to 27% in the hot and dry season. Similar findings had been published by Castro Ddel et al. (1994), who noted that in some districts of Buenos Aires the prevalence of lice declines from 56% in the relatively cold winter to 12% in the dry hot summer. Results of Toloza et al. (2009) showed that high prevalence rates still occur in Argentina throughout the year (19–42%), while in some schools in Germany/Europe/the United States there is always an increase in the number of louse-infested kids just after school holidays (Bauer et al., 2009). Due to control methods—always dependent on the financial means of the patients—initial infection rates decrease during the year or not.

How to diagnose infestations with head lice

Infestation with lice is a hidden process, which is usually only noted weeks or even months after its start. This is because almost 1 month is required until a fertilized female louse that has switched from one head to another host, has given rise to its progeny, which needs 17–21 days to reach maturity. Furthermore, the early bites of a few lice do not introduce the typical allergic reactions (i.e. itching at the biting sites), which mostly start after 4–6 weeks. For sensitive people the first symptoms of an infestation with head lice are the intensive crawling around of the newborn louse generation, often causing restlessness in the victims. Combined with the increase in the louse population on the head, the number of biting sites increases, appearing first as fine red dots of 1 mm in diameter, and later changing into a deep blue-red color and starting to itch. In general, these dots disappear within 8 days. However, in the case of bacterial superinfections (e.g. due to scratching) scars may be formed leading to pus-producing eczema—especially in cases of mass occurrence of lice. In these patients, the itching sensation increases dramatically and the hairs often stick tightly to each other. In such heavy infestations fever and lymph node swellings often occur because of the bacterial superinfections. However, significant proof of a louse infestation can only be shown by demonstrating the motile louse stages (crawling larvae and adults) and by detecting the nits (Figs. 5 and 6) at the base of the hair. If the hair is combed using a metal comb (the best is those with 4–5 cm long, 0.2 mm narrow teeth), the lice and their dark brown feces can be seen most easily when falling off onto a white towel. The occurrence of brilliant-white nits at the tips of the hair only indicates that there had been lice, since these nits are empty. Thus, the success of an anti-lice treatment is only assured by intensive combing for at least 15 min, since lice are motile and move quickly along the hair.

Symptoms of disease during head louse infestation

As described above, louse infestation may introduce no, slight or even severe symptoms of disease depending also on the different individual allergic reactions of the patients and the degree of bacterial or fungal superinfections.

Louse infestations may therefore result in a disease called pediculosis capitis, which is characterized by the following symptoms:

- inflammation at the biting sites (red/blue dots);
- itching leading to constant pain;
- eczema and excoriations;
- exudations;
- restlessness and poor sleep;
- slight to intense fever;
- swelling of lymph nodes;
- in severe cases (under extremely poor hygienic conditions and among people with immune suppression) eczema and the fluids of the exudations may cause plica polonica, where the hair becomes glued together into a tangled mass;
- in cases of superinfection of the wounds by bacteria (e.g. MRSA or Streptococcus) severe diseases may occur (Burgess, 2004; Meinking, 1999).

If lice-infested hosts contain agents of disease in their blood, head lice may also transmit them, as it is regularly established in body lice (which may be among the vectors of the Rickettsial disease “louse spotted typhus”). However, in the case of head lice, transmissions of agents of disease are much rarer than in body lice due to the fact that head lice change their hosts only rarely. Thus, mechanical transmissions (e.g. without intense reproduction inside the intestine of the louse) can only occur in crowded

camps (e.g. of prisoners, refugees, etc.) with many infected people (Bonilla et al., 2009; Robinson et al., 2003; Sasaki et al., 2006). However, since the agents of “trench fever” and “spotted louse borne fever” (with a lethal potency) have been found inside head lice, infestations with these ectoparasites should never be under-estimated.

Public reactions to head louse infestation and most common errors

Lice infestations on human heads are as old as mankind due to the common co-evolution that started millions of years ago (Fig. 1). Therefore, all human societies—even the most developed ones in the past and present—have to handle such infestations. Thus lice are described in the oldest human writings (e.g. in the 2nd book of Moses, in Egyptian papyrus papers, in the Talmud of early Jews, in Greek papers e.g. of Aristotle, in Arabian papers of Al-Qazwini, in medieval books and also in the famous drama “Faust” of the German poet Goethe, etc.). However, the methods of considering and handling lice infestations has differed in the social history of mankind. Of course, all victims suffered from the bite reactions and primarily considered these blood suckers as “nasty companions.” But they had to bear such infestations, because they could not avoid them. In former times the obvious correlations between social standards and hygiene of a victim were not realized—there are many reports of lice infestations of kings and rich people—thus there was no discrimination against infested victims. Lice infestation of men was even positively correlated with their sexual (“womanizing”) powers and attraction.

This attitude versus the “nasty” lice changed, however, when hygiene (starting in the 18th century) became a criterion of a high social standard. Then “louse infestation” was considered synonymous with dirtiness. With the constant increase in hygiene standards—especially in the rich, money-oriented Western societies—lice infestations became a psychological problem and even led to psychological diseases followed by completely incorrect responses. Since louse infestation is still considered as a sign of dirtiness and bad hygiene, louse infections are kept secret, so that other members of a group (e.g. kindergarten, school) may become unnoticeably infested. This makes the control of lice infestation very difficult. Therefore, high costs and a lot of useless efforts are accepted, although a head louse infection is much less important and dangerous compared to common diseases in children such as measles, diphtheria, whooping cough, etc.

This completely inaccurate view of a louse infestation is based on the following main errors:

1. Wrong: Lice only infect dirty people.
Right: Anybody can get lice, if there is hair-to-hair contact.
2. Wrong: Lice can be easily removed by combing and/or by using a “normal” shampoo.
Right: Even after intense combing some lice (e.g. larvae, nits) will remain and are not killed by normal shampoos.
3. Wrong: I can kill lice in a sauna or in a hot whirlpool.
Right: The temperature along the scalp (= biting site) is always ideal for the lice to survive.
4. Wrong: If I cut away the white brilliant nits, lice infestation will be stopped.
Right: These nits are already empty and the living lice stages suck blood at the scalp.
5. Wrong: Lice only occur just after the summer holidays in September and October.
Right: Lice occur during the whole year—there are constant reinfestations among the those in a group or family.
6. Wrong: If there is a louse infestation, nightclothes and bed sheets should be washed every day.
Right: This is pointless, since lice only occasionally leave a warm head in the direction of a colder sheet. Furthermore, lice die by desiccation within a few hours.
7. Wrong: I do not have to inform those in charge in the kindergarten or the mothers of my child’s friends in case of louse infestation, because I will treat it.
Right: The whole group should be checked and treated if necessary. Otherwise reinfestations may occur immediately after a successful treatment of a child.
8. Wrong: Vinegar will kill lice inside hair.
Right: The concentration of normal = diluted vinegar will not kill lice. Higher concentrations are even dangerous for health!
9. Wrong: Any anti-lice shampoo on the market will control head lice.
Right: There are many completely useless products and in addition many dangerous ones (inflammable, harming the lungs, skin). Furthermore, lice have developed resistance to some active compounds (e.g. permethrin, allethrin, malathion, etc.).
10. Wrong: All anti-lice shampoos also kill the developing larvae inside nits.
Right: Most of the anti-lice products do not enter the nits. Thus the larvae hatch unchanged. 2–9 days after the treatment (depending on their age during treatment). Therefore you will usually have to treat children two or even three times within a period of 9–10 days.
11. Wrong: If I have treated my child against lice, he/she will be protected.
Right: The child may become re-infested the next morning after treatment, if there is contact with the lice-infested hair of another person.
12. Wrong: Within a family only the lice-infested child has to be treated.
Right: All members of the family must be treated, since one of them may have a recent and thus still hidden infestation.

Head louse control

Historical approaches and mechanical delousing

Although infestation with head lice does not constitute a serious disease, it is not merely a nuisance. In the “cultivated” societies of today infected people are often plagued by social stigma, embarrassment, low self-esteem, disgust and/or rejection. Therefore, mankind has tried since early times to develop methods to get rid of these nasty bloodsuckers. Thus, in the oldest societies people collected lice from the hair of family members and ate them. The same is done by monkeys, with members of the lower hierarchy peel the hair of dominant members. In many early societies, but even until today, complete hair removal (i.e. shaving the head and the body as did the Egyptian priests every 3 days) has been a common method of eliminating head and body lice. However, although effective, the cosmetic and social results of this rough method is less than desirable, especially for school-going teenagers. This practice might be helpful among groups of soldiers or prisoners, but even then it was not commonly used in the Middle Ages. In former times, primitive and also highly sophisticated societies used plant oils, butter, mayonnaise and/or fine crystalline sand particles to suffocate the lice stages. These practices were used until chemical remedies were developed by analytical and synthetic methods at the beginning of the 19th century. Mechanical delousing by combing wet hair (that stops motility of the lice) gets the best results, if a metal comb with 4–5 cm long teeth at a very narrow distance (0.2 mm) is used. The combing must be done for at least 20 min. Even then delousing remains incomplete, always leaving some tiny larval stages plus many of the nits. The latter are strongly attached to the hair and thus withstand combing.

Chemical remedies

Apart from fleas, lice are the insects that most frequently plague humans. Although their immediate potential as vectors of agents of diseases is rather low, lice infestations cause enormous stress within families and their elimination requires huge efforts and considerable financial expenditure. This explains why mankind and later specialized chemistry companies tried to develop specific chemicals as anti-lice medicaments or tried to use existing chemical compounds as pediculicides and/or ovicides. At the beginning of the industrial century diluted vinegar, petroleum (= light oils), kerosene or different paraffins (= saturated C_nH_{2n+2} -compounds) were used in addition to vinegar, olive oil, mayonnaise, isopropyl alcohol (~70% by volume) or even different variations of jellies, which often did not work and which had many health-threatening side effects.

Insecticidal compounds

As far as insecticidal activity is concerned, there should always be controls carried out over the course of about 22–24 h. When incubating lice just in tap water, they contract their legs, remain immotile for minutes, but recover practically in 100% of the cases (own experiments). These results were confirmed by Mougabure-Cueto and Picollo (2010), who immersed lice in distilled water for 2 or 10 min. Even then more than 98% were found living after 22 h. The immersion of lice in 70% ethanol for 2 or 10 min showed some adverse effects in 30–35% of the lice 7–8 h after incubation in either of the 2 or 10 min exposed groups. However, many of them recovered after 22 h (Mougabure-Cueto and Picollo, 2010). These experiments clearly show that stronger measures are needed in the control of lice and that efficacy control must be carried out until 22–24 h after treatment. The actual situation of the pharmacological therapies around the world is rather obscure, since the efficacy of many of the different substances, that have been used often for more than 50 years, has decreased considerably in several countries on the one hand. On the other hand, many of these products turned out to cause side effects which threaten the health of users and/or the entire environment. This resulted in health authorities of different countries or regions (e.g. Australia, the United States, European Community) making a different assessment of the balance between usefulness and risks for the population. These different official considerations and deliberations finally ended in completely different governmental regulations with respect to the use and sale of the available active compounds in the different countries. Thus, in some countries a product that is sold in some countries over the counter (OTC products, especially medications), is only available on prescription in others or even completely banned from the market (Table 1). Furthermore, the situation may change at any time during the next few years.

Therefore, the present review first considers the efficacy of the available pharmacological anti-lice products, which of course may differ depending on the situation in the various countries according to the frequency of use, or on the recommended dose or mode of application respectively.

Lindane

Lindane, which belongs to the group of gamma-benzene hexachlorides, was developed to protect plants from the relevant pests and was widely used until it was banned for agricultural application in many countries. It acts in larval and adult lice in the same way as in the plant pests by inhibition of the so-called GABA receptor, which is an inhibitory neurotransmitter. This leads to a neuronal hyperstimulation of the insect followed by paralysis, thus stopping any feeding activity (e.g. blood sucking in the case of lice). This efficacy explains why lindane acts mainly on the motile stages of lice and thus is a pediculicide rather than an ovicide acting on the stages in the nits. During recent years there have been an increasing number of reports showing that many insects have developed resistance to lindane (Meinking et al., 1986, 2001, 2002, 2004, 2007). The lindane resistance is based on mutations inside the GABA receptor, which make it less sensitive to GABA antagonists.

Due to its chemical activity lindane may act neurotoxically not only in insects but also in mammals. Therefore, in the United States it carries a black box warning sign and was recently forbidden and outlawed in the EU due to this potential health risk. Lindane was labeled (to combat head lice) just for a single use and a very short application period of only 4 min, which in practice is

Table 1 Examples of pharmacologically-acting anti-lice products (AUS = Australia; EU = European Community; FRA = France; NL = the Netherlands; SA = South Africa; UK = United Kingdom; USA = United States of America).

Trade name	Country	Active compounds	Inflammability

Mosquito Louse Shampoo EU	EU	cocoamido-propylbetaine	No
Parasidose	FRA	biococcidine	?
Para speciaal Spray	NL, SA	Bioallethrine + piperonyl butoxide	Yes
Stromectol (officially for scabies)	FRA	ivermectin	?

usually much longer, since it takes time to disperse the product all over the hair. Even if lindane is used against non-resistant lice, this single short application will not eradicate the head lice and according to many researchers lindane requires at least 2, if not 3, treatments to eliminate the head louse infestation (Lebwohl and Levitt 2007). This rise in the number of treatments, however, increases the risk of health problems—on the package leaflet repeated treatments are deemed too risky because of neurotoxicity. Furthermore, a double or even triple treatment would entail enormous costs for the user (a single bottle of the lindane product was said to cost \$125; Lebwohl and Levitt, 2007).

Pyrethrins and pyrethroids

The pyrethrins are obtained from flower head extracts from the plant *Chrysanthemum* (former genus name: *Pyrethrum cinerariaefolium*) and are mainly extruded from the so-called pyrethrum component of this plant. The pyrethroids are synthetically produced pyrethrins and contain a large number of insecticides belonging to up to four generations due to their time of development. Permethrin, allethrin, phenothrin and many others have been (and some are still today) excellent insecticides with quite low toxicity to mammals due to their rather poor skin absorption and their rapid degradation to non-toxic metabolites during human metabolism. Both groups—naturally obtained ones or synthesized compounds—affect the voltage-gated sodium channels, where they introduce delayed repolarization of the neuron by blocking the closure of the sodium channel (VGSC; Clark, 2009). This leads (as in lindane) to a paralyzing effect on the muscles of lice, which impedes their blood sucking activities. While the synthesized pyrethroids (e.g. permethrin) are used as a main active ingredient in many insecticidal products, the naturally extracted pyrethrins (like the pyrethrum itself) are mostly used in combination with additional compounds, increasing the efficacy in their role as synergists. For example, piperonyl butoxide is often used in many products as a synergist, since it inhibits microsomal enzymes that would catabolize the pyrethrins inside the lice.

The main problem with the use of pyrethroids (i.e. the increasing resistance among insects) is spreading worldwide. The *kdr* in particular is rather high and based on a process that also occurs in DEET resistance. This resistance has its source in a mutation of the alpha-subunit gene of the neuronal VGSC, thus decreasing the sensitivity of the channel to pyrethroids and as a consequence, reducing the knock-down effect (i.e. killing effect). Therefore, the survivors with such a mutation will continue to reproduce, while the number of pyrethrin-sensitive lice will constantly decrease. Even the addition of piperonyl butoxide will not help to solve this problem, since it is only able to block the degradation of the now ineffective pyrethrin/pyrethroid (Kristensen 2005; Kristensen et al., 2006; Lee et al., 2000, 2003). Another way in which to produce resistance among lice to pyrethroids is because some louse populations have increased their amounts of glutathione-S-transferase and different mono-oxygenases, which are able to help in metabolizing the pyrethrins/pyrethroids. In the meantime, three louse mutations were found that lead to pyrethroid resistance. The most important of these is the amino-sequence position T 9291 (Clark, 2009).

It is therefore not surprising that reports on increasing resistance among lice to pyrethrins/ pyrethroids have become more numerous since the early 1970s, when the pyrethroids were registered as pediculicides. Broader existence of pyrethroid-resistant lice strains has been reported in France (1994, 2007), Czech Republic (1995), Israel (1995), Argentina (1998), the United Kingdom (1999), the United States (1999), Japan (2003), Australia (2003), Denmark (2005, 2006) (Barrios et al., 2010; Chosidow et al., 1994; Clark 2009; Durand et al., 2007; Gao et al., 2003; Gur and Schneeweiss 2009; Hemingway et al., 1999; Kristensen et al., 2006; Lebwohl and Levitt 2007; Mumcuoglu et al., 1995; Toloza et al., 2010; Yoon et al., 2003, 2004). The reduction of efficacy of permethrin, for example, was found in some studies to be extremely low, achieving louse-free heads in only 25% of the treated patients in Australia (Barker and Altman 2010).

Therefore, it is rather astonishing that under these conditions some US authorities and scientific authors recommend a three-time use of 1% permethrin, which nevertheless amounts to costs of around \$160 per treatment (including costs for medical care

plus loss of income due to staying at home). The market position of pyrethrin products is extremely high in the United States (Clark, 2009):

- Pyrethroids (e.g. NIX = 1% permethrin cream rinse) represents about 16% of the sales;
- Synergized pyrethrins (with piperonyl butoxide) have up to 40% of the market share (Table 1).

In order to avoid the disadvantages of the increasing resistance of lice to the pyrethrins/pyrethroids and since these compounds have low—if any—ovicidal activity, a three-fold treatment is recommended on days 0–7 and 13–15 based on the data concerning the louse development on an infested head. A two-fold treatment has often failed in the past. Meinking et al. (2004, 2006) found only 45–65% efficacy when treating with permethrin 1% on day 0 and 7.

Malathion

Malathion is inflammable and belongs to the group of organophosphates (phosphoric esters). It acquired its generic name from its smell of “bad sulfur.” Due to the generally bad effect of organophosphates on human health, malathion is not a very common ingredient of anti-lice products sold in the industrial countries. Thus, there is only one pharmaceutical preparation in the United States containing malathion (at a concentration 0.5% diluted in 78% isopropyl alcohol and 12% terpineol) at a rather exorbitant price of about \$125/per bottle. Malathion is also used in the United Kingdom, France, Australia and Denmark (Table 1).

Malathion is converted inside lice into malaoxon, which irreversibly blocks acetylcholinesterases. The subsequent increase in cholinergic activity brings about an enormous neuronal hyperexcitability that stops the feeding activity of the lice (Lebwohl and Levitt, 2007). If malathion resistance occurs (reported in the United Kingdom, France, the United States, Denmark, Australia (Burgess 1995, 2005; Downs et al., 1999, 2002; Gao et al., 2006; Hunter and Barker 2003; Izra and Brière, 1995; Kristensen et al., 2006; Yoon et al., 2004), apparently increasing levels of carboxylesterases are produced, which metabolize malathion into non-malaoxon intermediates. As a consequence, acetylcholinesterase remains at higher levels, cholinergic activity remains low and feeding of the lice remains possible. In the United States, the malathion product (Ovide) contains 78% isopropyl and 12% terpineol and so the hair is easily inflammable, if wet. The isopropyl alcohol acts synergistically by degrading louse proteins in the eggs and motile stages, while the tea tree extract (terpineol) inhibits both acetylcholinesterase and octopamine receptors and thus leads to neuronal hyperactivity and death. The whole product is fluid and thus can enter the aeropyles of the louse eggs and kill the developing lice inside the eggs. Therefore, in the United States approximately 80% of users are cured with a single application. Nevertheless, the official recommendation is a double application at an interval of 7 days. This is, however, a rather expensive “luxury” for the patient at a cost of \$125 per bottle. This treatment is recommended in the United States by the FDA for first-line use, but is only available on prescription, while in the United Kingdom it is an OTC product. Health might be endangered, if malathion is unintentionally swallowed; however, this is apparently rare due to the bad smell of malathion (Centers for Disease Control and Prevention, 2005). While in the United States over a period of 5 years (1998–2003) there were 50 cases of malathion misuse, over 300 and over 700 were recorded for pyrethroids and lindane misuse, respectively. Nevertheless—especially when looking at the reported malathion toxicity in the 1970s (Lebwohl and Levitt 2007), strict precautions are required.

Ivermectin

The chemical compound ivermectin belongs to the group of avermectins, which were originally isolated from the fungus of the *Streptomyces avermitilis* group by Professor Saitoshi Omura (Japan, Kitasato University). Ivermectin and related mectins were found to act systemically, thus it also enters tissues and may kill parasites there. Therefore, it was demonstrated that ivermectin not only kills intestinal and tissue-based round worms, but also mites such as *Sarcoptes scabiei* and *Demodex folliculorum*, which parasitize the epidermis of human and animal hosts. This effect is reached when ivermectin is orally consumed or if it is applied to the skin. Due to the efficacy of the avermectins, they were also tested as an anti-lice product, since they should be present in the blood, otherwise they would not have reached intestinal or tissue worms after topical application. Tests show that the normal “anti-worm dose” (= 0.2 mg/kg bodyweight) is sufficient to kill lice, when taken up orally (Glaziou et al., 1994; Meinking, 1999; Ribeiro et al., 2005). Thus, there are products on the market (e.g. in France), which also claim to control head lice in addition to scabies mites, if used on days 0, 7 and 13 (Table 1). Ivermectin acts on its targets (nematodes, mites, insects) by inducing an influx of chloride ions into the neurons, which causes paralysis of the parasites. Since head lice have to take up blood at least every 3–6 h, they die soon after feeding.

Trimethoprim and/or sulfamethoxazole

Head lice carry important symbiotic microorganisms inside their intestines and inside their sexual extruding channels (to be transferred to the progeny). These bacteria depend on the B-vitamin or other compounds, which might be produced by these bacteria. Therefore, several trials have been conducted using antibacterial compounds in order to control lice (Hipolito et al., 2001; Shashindran et al., 1978; Sim et al., 2003).

Suffocating chemical compounds

Today, chemical remedies that block the oxygen uptake of lice are making progress in the market for anti-lice products (Table 2), since pediculicidal-insecticidal products are posing more and more problems due to increasing resistance and/or due to their

Table 2 Examples of chemical louse-suffocating products (AUS, Australia; EU, European Community; FRA, France; UK, United Kingdom; USA, United States of America).

Trade name	Country	Active compounds	Inflammability

Ulesfia	USA	Benzyl alcohol	Probably
NeutraLice Advance	AUS	Benzyl alcohol, mineral oil, triethanolamine, etc.	Probably

health-threatening side effects. Previous non-pharmacological approaches such as the use of butter, mayonnaise, paraffin/petroleum jelly, olive oil, etc., tended towards the same direction, but in general failed to eradicate lice to any considerable degree, since lice were able to survive even for 5–6 h, if the openings (spiracles, stigma) of their tracheoles (= air transporting system) became mechanically closed. This is because sufficient oxygen remains in the network of the large and finest tracheoles in the interior of the lice, which—in case of occlusion—stop their motility and thus reduce the need for metabolic activity. In addition, these former occlusion materials did not hit the eggs (nits) significantly, so the larvae continued their development until hatching.

Di- and cyclomethicones

Today di- and cyclomethicones are used in combination with a variety of solvents. These cyclo- and dimethicones are used in many cosmetic skin care products, e.g. conditioners and hair repair products, since they are known to produce fine films on the skin and/or on hair. Therefore, they are also used in anti-lice products, where they should cover the openings (stigma) of the respiratory system, which are found at the lateral sides of the thoracic and abdominal segments 3–8 (see Section [Morphology of head lice \(*Pediculus humanus capitis*\)](#)). These di- and/or cyclomethicone containing products usually need very high concentrations of up to 94% and long exposure periods of up to 12 h to kill the lice, since they apparently do not enter the tracheoles, but cover only the outer openings. These products often glue the hair together, and at the end of the long exposure period a shampoo is required to clean the hair and enable combing. Some other products add diluting substances to the di- and/or cyclomethicone containing product. For example, some products contain high percentages of alcohol, dodecanol, isopropyl myristate to make the products more fluid, so that they can enter the tiny channels (tracheoles) of the respiratory system of the lice. These additions mean that the lice are killed within about 20 min at most.

The use of these di- or cyclomethicones, however, has several serious disadvantages, which might even affect the health of users (Table 2):

- Cyclomethicones (syn. cyclopentasiloxane) are highly volatile, which makes them useful as carriers for other ingredients. However, this property also means that they are highly inflammable. Therefore, there are clear warnings (Lotioncrafter, USA) “to avoid vapor inhalation” and “keep away from sources of ignition” (Tables 2 and 3).
- Even if the product itself is not inflammable, the combination of “hair plus product” may catch fire. Several severe cases in Germany, Austria and the Netherlands have led to government warnings.
- These di- and cyclomethicones are known to produce fine films. This is—of course—not important on the skin or on hair, but if they are inhaled, the same might occur on the surface of the lung epithelial cells thus endangering children treated overnight with such a product.
- Similar effects have been described with dodecanol-diluted products. They are not toxic, if ingested, but the inhalation, for example, of 0.2 mL dodecanol killed 9 of 10 rats within 30 min.

Table 3 Examples of flashpoints of different pediculicidal compounds (= minimum temperature for which the concentration of steam is sufficient to produce a detonation in contact with a flame or flash).

Pediculicides	Flash point
Coconut oil + isopropyl alcohol	17 °C
Citronella oil + dimethicones	37 °C
Dimethicones without hair	83.2 °C
Cyclomethicones without hair	77 °C
Di- and cyclomethicones with hair (depending on the mixture)	~37 °C

- The diluting compound isopropylmyristate is used in some products to spread the active antilice compounds. Due to this efficacy inhaling should be avoided here too.
- Although the Cosmetic Ingredient Export Panel of Germany considered it unlikely that these polymers would be significantly absorbed into the skin, there are cited cases where a cream formulation with only 1% dimethicone had severe adverse effects (Nair, 2003). This shows that di- or cyclomethicones may cause harm, if they are transported by carrier substances into the skin.
- These di- and cyclomethicones, when contained in products with a low fluidity, are often not fully effective and thus there is no quick and easy use, if full activity is the aim.
- Dimethicones (syn. Polydimethylsiloxane, PDMS) belong to a group of polymeric organosilicon compounds. Dimethicones are optically clear, considered as inert and thus are used in contact lenses, lubricating oils, or in products that make hair shiny and slippery, but also as occlusives such as hair repair products. According to the Environment Canada Domestic Substance List dimethicones are “expected to be toxic or harmful” and “suspected to be an environmental toxin and be persistent or bioaccumulative.”

However, these di- and cyclomethicones have the advantage over true chemical insecticides, in that resistance may not occur, as is the case in treatment with permethrin, allethrin, malathion and/or the widely banned lindane (Mougabure-Cueto et al., 2008; Picollo et al., 2000; Vassena et al., 2003).

Benzyl alcohol

Benzyl alcohol (synonyms: hydroxytoluol, phenylcarbinol, phenylmethanol) is generally used as a solvent in the production of perfumes, paints and adhesives, etc. In nature it occurs in the flowers of jasmine (up to 6%), carnation, etc. It is reported that this compound may produce together with air explosive mixtures including benzaldehyde, which acts narcotically. The explosive limit is at 20 °C, 1.8–16.3 vol%. Its toxicity is 2–3 times higher than that of isopropanol. The local reactions seen on the skin are flush and irritations, while inhaling may induce vomiting, headache, diarrhea, and/or collapse.

The activity of benzyl alcohol on head lice was reported by Meinking et al. (2010) when testing the United States product Ulesfia, which contains 5% benzyl alcohol (Table 2). It was shown in their tests that the benzyl alcohol blocks the closing (= contraction) of the spiracles (= stigma = the external entry openings of the breathing system of the lice), so that the non-pharmacological substances of the product (mineral oils, etc.) may enter and asphyxiate the lice by covering the exchange region between cells and free oxygen. These effects are documented even after an exposure of only 10 min. Of course, the efficacy is not neurotoxic as is correctly stated by the FDA, but the potential side effects of the benzyl alcohol are considerable.

Oxyphthirine

This product, which is registered in lists 03 and 05 of the International Classification of Goods and Services for the Purposes of the Registration of Marks, is composed of a patented vector which encapsulates a combination of triglycerides, isohexadecane, sorbitan ester and water (Table 2). This galenic lotion is claimed to be able to enter the orifices of the tracheal system of the motile louse stages and should also penetrate the nits via their aeropyles thus suffocating the developmental stages inside. A clinical study by De Sousa et al. (2010) carried out in 2007 in Fortaleza (Brazil) reported a complete cure in 82 of 82 children and a 97.5% killing rate of the nits, if the treatment time was 8–24 h. However, when using shorter treatment periods, this formulation failed. Heukelbach et al. (2009) showed that after 3 min only 22–54% of the lice were killed. Abdel-Ghaffar et al. (2010b) found no effects even after an exposure of 10–20 min, which are normal convenient treating times for users. Thus, longer exposition times of at least 8 h are needed in the case of Oxyphthirine.

Minerals in nanoparticles

Advances in nanotechnology offer further possibilities in the fight against ectoparasites. Thus there is already the technology to include chemical insecticides in tiny nanoparticles, which keep the active ingredients available for a long time (e.g. at the walls of indoor stables) (Mehlhorn and Mehlhorn, 2009). This saves money due to the reduction in the required spraying action and also reduces the danger of intoxication from bodily contact. Recent trials using ZnO nanoparticles (made by mixing zinc nitrate and sodium hydroxide with soluble starch as a stabilizing agent; Kirthy et al., 2011) were promising, since even low concentrations, when brought in vitro onto the head lice, achieved a killing rate of 100% after an exposure time of only 1 h. However, further tests are needed to ascertain whether the same killing rate is achieved when lice hidden among hair are treated. Furthermore, tests are required to see whether those inhaling the tiny nanoparticles during treatment and/or exposition period get lung problems. A covering of the surface of the lung alveoles with such nanoparticles might have considerable implications.

Carbaryl

This compound is a chemical in the carbamate family. It is the third most used insecticide in the United States to control pests in domestic gardens and commercial agriculture. In the late 1960s it was also used in the control of head lice and became available in United Kingdom as a lotion (Carylterm) or as shampoo (New Suleo). Its action against lice is based on its efficacy in inhibiting cholinesterases. At first this compound was classified as “moderately hazardous.” However, when in recent years it turned out that carbaryl may be carcinogenic, it was retracted from the market, and there are no recent products available in the United Kingdom.

Plant-derived remedies

During the billions of years of evolution on earth, plants, which depend strongly on their fixed habitats, have had to develop means that would protect them against the attacks of other plants and against the feeding activities of insects, in order to survive. These supporting substances inside plants were later used by humans as precursors of medicaments and also against plant or body pests either by applying them directly, as naturally obtained extracts or by synthesizing particular ingredients, such as the pyrethrins/pyrethroids (Amer-Krim and Mehlhorn, 2006; Casida and Quishad, 1995; Food and Agricultural Association of the United Nations (FAO), 1995; Mehlhorn et al., 2005; Schmutterer, 2002; Semmler et al., 2009).

Only in the case of synthesized single substances were studies successful in defining the mode of action against mites, ticks or insects (including lice), while the activity of isolated extracts, which always contain a mixture of single, potentially active substances, was only poorly understood. The activity of extracts is also depended on the concentration used and the method of application. Thus, in the following two sections the mode of action of the selected plant extracts is either unknown, suggested and/or rather superficially understood.

Insecticidal compounds

Essential oils obtained by various methods from plants (e.g. from seeds, flowers, bark, stem, leaf, and/or roots) have been in use since mankind began undertaking cultural activities. Thus billions of humans use these oils daily for cosmetic purposes, while their use as medical or pesticidal devices is much less common, although increasing today. With respect to the control of head lice infestations, there are many products on the market (Table 4). In general, mixtures of different plant extracts are used and combined into a product in order to get a standardized formulation, which brings constant results. However, although a large variety of plant extracts are used, significant and comparable trials are rather rare. There are reports on the efficacy of mixtures containing 10% (w/v) *Melaleuca* (= tea tree) oil and lavender oil (w/v) (NeutraLice, Australia) with an efficacy of 97.56% (Barker and Altman, 2010) exceeding the 82.5% efficacy of a mixture of other essential oils (MOOV solution, Australia; Grieve et al., 2007). The efficacy of essential oils depend on the method of extraction, on the application dose, on the plant species and on the selected plant organ. This has been shown by many authors. For example, Toloza et al. (2010) reported that essential oils of four different *Eucalyptus* species needed between 47 and 112 min to kill 90% of the head lice in their test system. This is not surprising, since the different compounds in two different *Eucalyptus* species (*E. dunnii*, *E. gunnii*) varied considerably. For instance, 1.8 cineole was found in a ratio of 49.59–26.67% in identical chromatograms of both plants. Sunilson et al. (2009) showed that the mode of extraction also makes a big difference in efficacy. In the case of petroleum, they obtained using ether extracts of leaves of the Indian tree *Pongamia pinnata* lice killing rates between 50% and 100%, while methanol- or chloroform extracts revealed only low efficacy rates. The combination of essential oils in general brings better results than higher concentrations of a single oil. The in vitro and in vivo study of Prasutr et al. (2010) on a product called Biomimic lice lotion showed in vitro full (100%) ovicide activity. The pediculicide activity was 100% in vitro in three trials, but only reached 84% in a fourth. Both—eggs and motile lice—had been incubated for 30 min. When looking at the in vivo results, the activity of motile lice was around 90%. Similarly, however, varying efficacy rates were reported from oils of *Eugenia caryophyllata* and other plants (Yang et al., 2004, 2005). All these tests have to be considered under similar testing conditions.

Although there are definite proofs that essential oils may kill lice, their mode of action is unknown and generally only described as “fumigant activity” (Barker and Altman, 2010), since it was observed that there are a lot of volatile components in these oils, which are also called “etheric oils.” This effect was demonstrated to increase, if the patient wears a shower cap, so that the lice and eggs remain under complete “oil-air pressure.”

Table 4 Body characteristics of lice of humans.

Characteristics	<i>Pediculus humanus capitis</i>	<i>Pediculus humanus corporis</i>	<i>Phthirus pubis</i>
Size (length, mm)	♂~2.4–2.5 ♀~2.6	♂~2.7–3.8 ♀~3.8–4.8	♂ 1.3–1.6 ♀ 1.3–1.6
Antennae	4 short, strong segments arising from a strong shaft	4 short, strong segments arising from a strong shaft	4 short, strong segments arising from a strong shaft
Breast	Breast is smaller than hind body	Breast and hind body appear ovoid	Fused in part with short hind body, appears square-like
Shape of eyes	On both sides of the head a simple ocellus for dark-light seeing	On both sides of the head a simple ocellus for dark-light seeing	On both sides of the head a simple ocellus for dark-light seeing
Abdomen	Small, relatively deep lateral notches	Broad, not so deep notches	Appears nearly quadratic, no clear separation between breast and hind body
Sites of parasitizing	Mainly on hair of head, rarely also on hair of breast, beard, eyebrows, armpits	Mainly on body hair and on inner side of clothes, very rare in head	Mainly on pubic hair, rarely on eyebrows, hair of breast and armpits
Place of the pores of the operculum (egg cover)	On 4/5 of the whole place	On 4/5 of the whole place	Operculum is fully covered by pores

This method not only helps to increase the efficacy, but also protects the patient from the side effects of inhaling such high concentrations of those essential oils. Therefore, it is strongly recommended to check the potential side effects of certain essential oils before using them at high concentrations (Tolozan et al., 2010). This is underlined by the report of Barker and Altman (2010), who reported that 29 out of 132 patients suffered adverse reactions after a treatment with 12% tea tree oil and lavender, but only 3 or 4 suffered adverse reactions when treated either with benzyl alcohol plus mineral oil or with pyrethrins respectively.

Suffocating compounds

This section deals with extracts of neem tree seeds and grapefruit (Table 5) in combination with a patented activity of dibasic esters. Of course, it is known that components of neem and grapefruit may have insecticidal activities, if they are used in high concentrations (Schmutterer, 2002) due to their main components azadirachtin and flavonoids. The action of azadirachtin (e.g. on fleas and crop pests) was seen to proceed slowly, since this component prohibited feeding and egg deposition. Thus, this activity would be a pharmacological activity. Flavonoids have similar effects, which occur after constant and permanent application of high dosages (Adedapo et al., 2008). However, treatments for lice infestations require sudden effects (= a quick knock-down of motile stages). Therefore, a shampoo has been developed, which is based on rather low concentrations of azadirachtin (MelAza) and a combination of supporter compounds. This rather water-free but liquid shampoo (Abdel-Ghaffar and Semmler, 2007; Heukelbach et al., 2006) acts quickly and mechanically by entering the tracheal respiratory system of lice (and many other mites, ticks and insects (Abdel-Ghaffar et al., 2008; Semmler et al., 2009)). At the terminal end of tracheoles, where a fine aqueous (fluid) layer covers the membranes of the cells thus protecting them from desiccation, the electric loading of the neem-based anti-lice compound enables the closing of the terminal end of the respiratory system (Fig. 9). This was proven by transmission electron micrographs, showing three 5–10 µm sized gold particles, which had been mingled into the shampoo prior to the treatment of lice in vitro (H. Mehlhorn, unpublished data). Due to this activity the entrance of oxygen into the cell is suddenly interrupted and will be blocked until the insect dies. This process is therefore not based on pharmacological properties, but is simply a physical reaction.

A paper by Abdel-Ghaffar et al. (2010b) proved that a complete submersion of the lice into this neem-based shampoo for only 3 min is sufficient to kill 100% of the lice. This shows that the efficacy starts much quicker when using the more adhesive di- and cyclomethicones, which often only block the outer entrances (= spiracles, stigma) of the respiratory system leaving enough oxygen for a long survival period, during which the lice reduce their metabolism. Therefore the recovery rate of methicone-treated lice is high, if the treatment period is not long enough and if the products are washed off too early (by means of a normal shampoo). Nearly identical effects were seen when the neem extracts were replaced by grapefruit extracts (Abdel-Ghaffar et al., 2010a).

When using either the neem-based shampoo or the shampoo containing grapefruit, the larval stages inside the nits were also killed. However, this process took longer than 10 min. Apparently the developing stages need less oxygen, so they might survive oxygen starvation for at least 10–15 min. This was seen when cut-off nits were incubated in both shampoos and their development was followed in vitro for the next 7 days. However, in vivo treatment of nits may fail in some specimens, if these nits are not covered long enough (if at all) by the shampoo due to imperfect application of the product onto the hair. This survival of developmental stages within the nits would lead to persistence of an infestation in case of a single treatment. Therefore, a second course of treatment after 9–10 days seems reasonable. This second treatment would also extinguish new infestations with lice, which may occur if a perfectly treated child gets into hair-to-hair contact with untreated louse bearers (Al-Quraishy et al., 2015; Aspöck, 2010; Dörge et al., 2017; Iwamatsu et al., 2016; Pavela et al., 2016; Raoult and Roux, 1999; Sands et al., 2016; Sangaré et al., 2016; Semmler et al., 2017; Ulutasdemir et al., 2018; Yoon et al., 2015).

Table 5 Selected species.

Species	Host	Length	Suborder
<i>Bovicola bovis</i>	Cattle	1.5–2 mm	Ischnocera
<i>B. ovis</i>	Sheep	1.5–2 mm	Ischnocera
<i>B. caprae</i>	Goat	1.5 mm	Ischnocera
<i>Werneckiella equi equi</i>	Horse	2.0 mm	Ischnocera
<i>W. e. asini</i>	Donkey	1.8 mm	Ischnocera
<i>Trichodectes canis</i>	Dog/canids	2 mm	Ischnocera
<i>Felicola subrostratus</i>	Cats	1.35 mm	Ischnocera
<i>Anaticola anseris</i>	Goods	4 mm	Ischnocera
<i>Eomenacanthus stramineus</i>	Turkey/fowls	3.2 mm	Amblycera
<i>Menopon gallinae</i>	Chicken	1.8 mm	Amblycera
<i>Lipeurus caponis</i>	Chicken	2.3 mm	Ischnocera
<i>Columbicola columbae</i>	Pigeons	2.5 mm	Amblycera

Why is it so difficult to eradicate head lice completely?

The persistence of head lice even in societies with high hygienic standards and sufficient financial means to control them is based on many reasons and on the astonishing abilities of the lice:

- Head lice live hidden in hair and a transmission is noted only weeks to months after the infestation day.
- Due to their strong claws lice do not fall involuntarily from a host.
- Head lice deposit their eggs inside nits, which protect the developing larvae from falling off and from adverse influences (e.g. water, treatments).
- The glue used to fix the egg/nits to the hair is not water-soluble.
- Motile lice stages inside hair are very resistant to environmental influences. Even 70% alcohol does not kill them easily.
- Lice have developed resistance to many chemotherapeutical drugs, so that there are always survivors.
- Furthermore, control measurements using suffocating products fail to kill 100% of the louse population on an infested head, since often not all the hair is covered with the products.
- Even in cases of successful treatment, a re-infection may occur the next day from hair-to-hair contact with an untreated person.
- The time needed for completing the developmental cycle on a head varies considerably, so that at a given treatment period some lice stages may not come into contact with the product.
- In a population of humans there are always people who do not notify an infestation with lice and are thus a major reservoir for new infestations.
- Louse transmission is easy in today's crowded places (e.g. subways, sports events) or among playing children.
- Poor people cannot pay for anti-lice products and thus remain reservoirs. Other people—often with “green” ideology—do not use efficient products and thus also produce “happy survivors” among the nasty bloodsuckers.

Conclusions and perspectives

The present situation in the fight against head and body lice is characterized by the constant decreasing activity of chemotherapeutical remedies due to increasing resistance. This gap could be closed using chemical and/or natural products with suffocating activities. However, several of these innovative products do not fully work and thus leave reservoirs for new infections. Furthermore, many of the available anti-lice products on the global markets pose high health risks for users. These dangers are even increased if the products are wrongly used or when pharmaceutical companies avoid mentioning the dangers. It is hard to believe that on many products containing cyclo- and/or dimethicones or high percentages of inflammable substances, no warnings are given that these products are inflammable (Table 3) and that the fire can only be extinguished by covering with a towel, but not with water.

On the other hand, there are suffocating products made with neem extracts or flavonoids (see Table 4), which do not glue the hair, which are not inflammable, which do not touch the scalp and which smell rather nice. Therefore, the user should carefully read the product information leaflet before buying any anti-lice product.

Body lice (*Pediculus humanus corporis*)

1. Name: This species parasitizes on the human body surface sucking blood like their relatives, the head lice (*Pediculus humanus capitis*) and the pubic lice (*Phthirus pubis*). In some countries these body lice are also described by the Latin name *P. humanus vestimentorum* (=belonging to clothes). In Germany it is called “Kleiderlaus,” in France “Pou du corps” or “Pou blanc” and in Spain “Piojo di vestimento.”
2. Size: The adult males reach a length of 2.7–3.8 mm, while the females (Figs. 3 and 8) are 3–4.8 mm long. Their segmented antennae are considerably longer than those of males reaching a length of up to 0.4–0.5 mm (Fig. 3).
3. Body: The body of the lice is wingless and is clearly separated into three regions:
 - a. Head, which is provided with one pair of segmented antennae being composed of five segments bearing sensillae. At both lateral sides a single, rather primitive eye is located consisting of an enlarged, pigmented so-called ommatidium (Fig. 8). The mouthparts belong to the biting-sucking type. They are kept retracted in a sheath inside the mouth until the next bloodsucking.
 - b. Breast, which consists of three segments, each of which bears a pair of legs being each equipped with two claws, which may clutch ring-like together, so that a hair can be completely surrounded thus avoiding an accidental dropping down from the host's body. Each leg comprises six segments. At the proximal part closer to the thorax, they start with the coxa followed downwards by the trochanter, femur, tibia and tarsus. The lice are wingless, while in other insects the backside of two breast segments are each equipped with two wings.
 - c. Abdomen. The hind body of the body lice consists of originally 10 segments. The first two are strongly reduce and do not bear openings of the tracheal system, while starting from the third until the eight segment each has an opening (at the lateral side) of the tracheal breathing system, which is called stigma or spiracle. The terminal segments number nine and ten are (partially) fused forming one, which in case of females ends bifurcated and appears pointed in males.

Fig. 8 Micrograph of the anterior region of a *Pediculus humanus corporis* louse showing the two antennae with 4 segments and the two lens eyes, which possess a dark bottom.

4. Development: After copulation with males the females discharge whitish eggs (Fig. 5), which become attached at the hair close to the scalp. The eggs are slender reaching a length of 0.6–0.8 mm and are covered by a spherical to ovoid lid, which is removed by the larva at the end of its development. Two-thirds of this lid contain tiny openings, which at their inner side are covered by a fine membrane, which allows apparently a limited entrance of oxygen. This arrangement of the openings is very similar in head and body lice, which in history have common sources (Fig. 1). After 5–6 days the six-legged first larva hatches from its egg by removing the cover by help of their legs. They start sucking blood along the body of their hosts for 5–7 days and then they discharge their cuticle and then they form a new one, which hardens in a few hours. After another feeding period of 5–6 days they discharge again their cuticle and reach the third larval stage. After another hatching the adult stage is reached as male or female.
5. Transmission of lice: The body lice live on humans in regions between skin and clothes, where they are anchored by help of their claws. After copulation, the females glue their eggs at the base of the body hair of humans, but also onto the inner surface of clothes and onto the surface of bed covers, from where they may reach other hosts. The lice prefer temperatures between 31 and 33 °C, which are given in the space between skin and clothes or bedcovers. These temperatures are needed to produce and distribute eggs. However, they survive also lower and higher temperatures (10–50 °C). To lay eggs the females need at least one blood meal per day. If temperature and blood meals are given, the females lay about 5–14 eggs per day (Fig. 3), which they attach at human hair or clothes. Lice are killed, when clothes are exposed to at least 50 °C upwards. Females are able to produce up to 300 eggs during their normal adult life span of about 30–40 days, which might be prolonged, if contaminated clothes are stored at low temperatures (e.g. close to 0 °C).
6. Reactions on blood sucking: While sucking blood all lice stages (larvae, adults) introduce saliva into the biting site. This saliva contains components, which keep the ingested blood fluid, so that the channels of the mouthparts are not blocked by coagulating blood. The human skin develops reactions showing 1–1.5 mm sized dots, which at first appear slightly red and bluish. These biting sites develop itching reactions the intensity of which depends on the allergic status of the person hit by such lice. Since the itching might become very intensive in cases of infections with many lice, eczema might become developed and skin may appear brownish.
7. Transmission of agents of diseases: In contrast to the effects of head lice, which in general might be very nasty, but not very dangerous, the bites of body lice can be life threatening, since they are able to transmit agents of severe diseases.
 - a. Louse-borne spotted fever: This disease is initiated by transmission of the species *Rickettsia prowazekii*, which occurs in Europe, Asia and Africa. These stages have been first described in the year 1909 by the French scientist Charles Nicolle, who received 1929 the Nobel Prize for this discovery. In the year 1907 the American Howard Tyler Ricketts (1871–1910) described the fact that the agents of the so-called Rocky Mountains spotted fever looks very similar to those of the louse-borne spotted fever. He died already 1910 in Mexico due to this fever. The German scientist Stanislaus von Prowazek (1875–1915) confirmed Ricketts' results by experiments and noted the death of hundred thousands of soldiers of both sides occurred during the First World War (1914–18). He also died as consequence of a laboratory infection with this bacterium in the year 1915. Remembering the death of both (von Prowazek and Ricketts) the agent of this louse-borne disease was named *Rickettsia prowazekii*, which today is described as a gram negative, stick-like bacterium measuring $0.8\text{--}2 \times 0.3\text{--}0.5 \mu\text{m}$. These bacteria live exclusively inside cells of their hosts. In their vectors—body lice—they live in intestinal cells and are set free within dust-like feces. When humans inhale or ingest such bacteria, they enter endothelial cells of blood vessels and start reproduction. If such endothelial cells are destroyed, they enter other endothelial cells and reproduce themselves therein again.
 - b. The clinical signs of this disease start after an incubation period of about 10–14 days with a high graded fever for about 10 days accompanied by 2–4 cm sized skin dots, giddiness, limb pain, dizziness and cough. In times before the drugs doxycycline and several tetracyclines had been developed, the lethality rate was very high reaching “normally” 10–20%, but was even considerably higher among soldiers in the trenches of the European and American wars, where very large numbers

of soldiers died in the First World War in France and in various USA-South America wars. Today drugs like doxycycline (200 mg $\times$ 1), chloramphenicols and penicillin are very helpful. For pregnant women and children amoxicillin and erythromycin had been successfully used. If the diagnosis and the start of the treatment does not start soon after an infection, the death rate is significantly increased.

8. Further transmitted agents of diseases

- a. *Rickettsia mooseri*,
- b. *Bartonella quintana*,
- c. *Borrelia recurrentis*,
- d. *Francisella tularensis*,
- e. *Salmonella* sp.
- f. *Staphylococcus* spp.

9. Mode of transmission

Body lice are rather quickly moving animals, which are able to pass larger distances in rather short times (e.g. 35 cm/min), so that in hotels, clinics, etc. they may easily reach their hosts during night time, while their presence remains undiscovered. The female glue their eggs at the hair of persons and occasionally on the surface of resting places, which allow hatching larvae to get in contact to body sites of human hosts.

10. Protection measures

- a. Check lower side of beds when sleeping in foreign beds.
- b. Check remnants of blood on blankets, which occur potentially due to hidden lice.
- c. Check blankets for dark droplets, which may have their origin in the bloody feces of lice.
- d. Check presence of tiny blackish balls, which might be excreted lice feces.
- e. Wash clothes as well as blankets in hot water (60 °C).
- f. Ask a pest exterminator to spray insecticides or molt inhibitors.
- g. If the above listed measurements are not feasible, do not enter the room for at least 10 days and keep the temperatures low therein.
- h. The occurrence of body lice in an institution should be announced to the public health institutions, otherwise punishment will follow.

Attention: The stages of *Rickettsia prowazekii* lead to a chronical infection, so that even years after survival of a spotted fever attack a relapse may occur. Thus, the control of body lice, especially in institutions with huge numbers of humans on small space is very important to avoid epidemics of louse-borne diseases.

Pubic lice (*Phthirus pubis*)

1. Name: The genus name *Phthirus* (syn. *Phthirius*) has its origin in the Greek term "phtherein," which means "to destruct," while the species name "pubis" is of Latin origin and designates the female genital region. This explains, why in French language these lice are called "pou du mont pubis" or "papillion d'amour" = butterfly of love in English. In Italian language they are named "piattola," while the English world calls them "crab louse" describing its nearly quadratic body.
2. Biology: Adult males and females measure 1.3–1.6 mm in length and nearly the same in width (Fig. 4). The claws of the six legs are equipped with claws, which help that the lice may clutch at hair and thus become fixed thereon. After a development via three larval stages the adult female starts laying eggs for up to 26 days before they die. After 5–8 days the larvae hatch from the eggs, start sucking blood and passing the larval stages within 15–17 days they become adult and start propagation mainly in the pubic region of the human body, but they occur also on the eyebrows, eyelashes, armpits and beard.
3. Bites: The bites of these lice induce less intensive itching than do other lice species and they are often only noted when they have developed huge numbers of lice descendants.
4. Transmission: During sexual intercourse. These lice are mainly transmitted from person to person.
5. Removal: Since the lice clutch firmly at hair, the quickest solution of the problem of heavy infestation is to remove the lice from the hair at heavy infested sites by help of tweezers. However, mass occurrence of these lice should be treated by help of suffocating shampoos like Licener, which kill also the stages in the eggs.
6. Effects of bites: The bites induce only low-graded itching reactions. However, due to scratching at itching sites, eczema might become developed and the skin may appear bluish (in French "taches bleues").

Pig lice (*Haematopinus suis*)

The adults of this species reach a length of 4–6 mm (Fig. 9A and B). They are specialized to live on pigs, but in rural regions they are also found on farmers. The infection occurs when farmers hold such animals on their arms in order to stay on a balance and to find out the weight of a "nervous" piglet, which would not stay alone on a balance.

Fig. 9 Light (A) and electron microscopic (B) micrographs of the species *Haematopinus suis*, which may also reach human skin during work.

Mallophaga (Chewing lice, biting lice)

1. Name: Greek: mallos = wool; phagein = to consume, feed.
2. Geographical distribution: Worldwide in cases of dense animal farming they appear in masses and some of them attack also humans.
3. Agents of disease: The order Mallophaga (Table 5) contains two suborders: Amblycera and Ischnocera. They parasitize mainly on animals, while humans are rather seldom affected.
 - a. Ischnocera: Name: Greek: ischnos = thin; keras = horn/protrusion. Antennae: there are two antennae, which are clearly visible and possess—depending on the species—3–5 segments. Hosts: see Table 5.
 - b. Amblycera: Name: Greek: amblys = blunt; keras = horn. Antennae: They lie often in a fold of the head and thus are not or hardly visible. Hosts: see Table 5.

Besides the differences in the position of the antennae, the Amblycera possess only one claw at the feet, while feather chewing lice possess mostly two.

4. Symptoms of disease: Amblyceran species (Table 5) massive loss of blood may occur in highgraded infections. In cases with infectious ischnoceran species restlessness, strong itching and loss of hair/feathers is one of the most common symptoms.
5. Diagnosis: If animals show itching, observation of skin is required, i.e. looking for attached eggs: studying hair by help of a microscope. Detailed diagnosis is not needed, since all Mallophaga react on contact insecticides.
6. Pathway of infection: Body contact between infested and not infested specimens. These parasites may also pass onto the skin of humans, who then may suffer from the same symptoms like animals.
7. Prophylaxis: Spraying of typical insecticides onto animals or the biological agent MiteStop (produced by Alpha-Biocare GmbH, Neuss, Germany), which kills by drying the mallophages on mammals and the featherlings on birds (see Benelli et al., 2018 for a dedicated review on Mallophaga control).
8. Therapy: Macrolytic lactones have been proven to be successful against chewing and biting lice among the mallophages. In cases of infested humans normal shower shampoos are sufficient to clean the body.

Introduction

Laelapid and dermanyssid mites are two families belonging to the order Mesostigmata, one of the most morphologically and ecologically diverse and widespread order of Parasitiformes. Among this order, parasitic species are mainly grouped in one superfamily, the Dermanyssoidea (Dowling, 2006) where 11 families out of 17 comprise species parasites of vertebrate (Lindquist et al., 2009a,b). Laelapids and dermanyssids are two of these families showing a related evolutionary path and a worldwide distribution. Nevertheless, their medical and veterinary importance is very different.

Members of the laelapid family are very numerous and heterogeneous. They show a great variation of life-history strategies and associations. Several species are free-living predators in soil, others are nidicolous commensal, while others facultative or obligate ectoparasites in the nests and colonies of vertebrates and insects (e.g., Radovsky, 1985; Gettinger et al., 2005; Dowling and Oconnor, 2010; Lindquist et al., 2009b). Species that are blood-feeding parasites of commensal rodents have risen some interest. However, to date, only one species (*Laelaps echidninus* Berlese 1887) proved to have some sanitary relevance since involved in diseases transmission among rodents and suspected to be a vector of human pathogens (Mullen and Oconnor, 2019). On the other hand, considering the increasing populations of “peridomestic” rodents in urban and rural regions, the importance of the rodent associated laelapids is likely to increase as well.

A different scenario characterizes the dermanyssid family. They are a much more uniform group with all members obligate hematophagous ectoparasites of vertebrates (Lindquist et al., 2009b). Among this family, the genera *Liponyssoides* and *Dermanyssus* have a veterinary and medical interest. In particular, *Dermanyssus gallinae* (De Geer, 1778) has aroused the highest attention due to its enormous economic implications in the poultry industry, and its not negligible interest in human health. This article, after a first part focusing on aspects of systematics, evolution, and identification, discusses the complex biology and ecology of these two families, and highlights the medical and veterinary importance of the relevant species, together with the correct approach for their prevention and control.

Systematics, phylogenetic relationships and evolution

Among chelicerates, Acari (mites and ticks) are the most abundant and widespread taxon and the most diverse regarding life history patterns, behavior, external and internal morphology (Alberti and Coons, 1999; Krantz, 2009a,b). They comprise over 55,000 species described (Zhang, 2011) but 1 million species seems a very cautious estimate. The order Mesostigmata (or Gamasida) belongs to the superorder Parasitiformes (or Anactinotrichida), the smaller of the two main groups in which Acari are divided (Lindquist et al. (2009a,b)). The known fossil records for the Parasitiformes date back to the late Cretaceous Era, and ancestors of the superorder Parasitiformes probably made their terrestrial debut as predators in surface habitats of the littoral zone (Krantz, 2009a).

Mesostigmata is a monophyletic group (Li et al., 2019) comprising the largest number of species (over 11,000 species, Beaulieu et al., 2011), and it is the most ecologically diverse and geographically widespread order in Parasitiformes showing significant adaptive radiation into a broad spectrum of general niches. Fossils of mesostigmatid mites are very rare (only 15 records, including 4 named species) with the oldest record dated back to Paleogene Period (Dunlop et al., 2013, 2014).

The higher classification of Mesostigmata is still controversial. Here, we follow Lindquist et al. (2009a,b) and Beaulieu et al. (2011). Most species in the Mesostigmata are free-living predators and are beneficial, while some species have a parasitic behavior.

The ones associated with vertebrates have developed notably diverse host relationships, but nearly all are in one superfamily, the Dermanyssoidea (Dowling, 2006).

The Dermanyssoids include many species of free-living predators, which have given rise to a diverse range of families and genera that are closely associated with vertebrate and invertebrate hosts (Radovsky, 1969; Lindquist et al., 2009b). Derivative families include from commensals, phoretics, and symbionts, to facultative (e.g., Laelapidae) and even obligate blood-feeding ectoparasites (e.g., Laelapidae and Dermanyssidae) of vertebrates. Due to such wide ecological amplitude with high levels of morphological variability, it has been difficult to develop a robust phylogenetic hypothesis of dermanyssoids. However, as hypothesized by Radovsky (1969), the taxa present in the Dermanyssoidea appear to be derivative groups of a basic free-living stock represented by the subfamily Hypoaspidae (Laelapidae) while another subfamily, the Laelapinae (Laelapidae), appears to be the source of most of the other parasitic groups in the Dermanyssoidea. The same life cycle-feeding pattern present in dermanyssids and laelapids may be considered an additional indication of their evolution from a common ancestral protolaelapid type (Furman, 1966). Such evolutionary sequence, postulated for the Dermanyssoidea (Radovsky, 1969, 1985, 1994; Dowling, 2006; Krantz, 2009b; Lindquist et al., 2009b), was confirmed by molecular studies (Dowling and Oconnor, 2010).

The nesting habitat provided the basis for a close association between the mite and the nest occupant; such association may have initially been considered a kind of commensalism, i.e., mites feeding on small ectoparasites and/or on blood exuding from abrasions present on the body of the nest inhabitant. Later, specializations for strict parasitism have occurred because they give access to a more dependable and richer food supply than opportunistic feeding (Radovsky, 1994).

The adaptation to a closer parasitism is shown, for example, by the more and more specialization of the mouthparts (chela). In fact, while the primitive chelate-dentate state of some dermanyssoids (e.g., some species of *Androlaelaps* (Laelapidae)) is more efficient in grasping and shearing the prey, or other food than in piercing skin, the slender shape of the chelicerae and the presence of smaller teeth (e.g., the stylet-like chelicerae of Dermanyssidae) have driven to the hematophagous behavior of some other dermanyssoids, thus providing a more efficient host-parasite relationship. Furthermore, a reduction of the dorsal sclerotization and of the dorsal shield occurred increasing the capacity for engorgement (e.g., in Dermanyssidae, Macronyssidae and Haemogamasidae). The development of relatively long, slender legs is also associated with an increased capacity for engorgement. In fact, the body expansion sometimes is enormous and short legs would not have been able to carry it (as in the case of Dermanyssidae) (Radovsky, 1969, 1985, 1994; Krantz, 2009b; Lindquist et al., 2009b).

In the Dermanyssoidea, the intermediate gradations between the free-living and the obligatory parasitic behavior are well represented by extant species: e.g., the genera *Haemogamasus* and *Androlaelaps* (Laelapidae) include predatory species but exhibit varying degrees of dependence on a diversity of vertebrate hosts (from nidicoles to facultative, to obligatory hematophagous parasites), and the Laelapidae and Haemogamasidae show a graded transition from predatory to parasitic mites, strongly indicating that the transition began with opportunistic feeding in the vertebrate nest environment. On the other hand, these families show a lack of specific morphological modifications to parasitism. Indeed, displaying varying levels of blood-feeding and host dependence (Radovsky, 1994; Dowling, 2006).

Among the 17 families recognized in the Dermanyssoidea (Beaulieu et al., 2011), 11 families comprise vertebrate parasites (Lindquist et al., 2009b); the present chapter focuses on the families Laelapidae and Dermanyssidae, which also include ectoparasites of several terrestrial vertebrate taxa (Krantz, 2009b) (Table 1).

Table 1 Systematic classification of the families Dermanyssidae and Laelapidae according to Lindquist et al. (2009a,b) and Beaulieu et al. (2011).

Taxonomic category	Name	Notes
Superorder	<i>Parasitiformes</i> Reuter, 1909 (or Anactinotrichida)	
Order	<i>Mesostigmata</i> G. Canestrini, 1891 (or Gamasida)	Divided into three suborders
Suborder	<i>Monogynaspida</i> Camin & Gorirossi, 1955	Largest and most speciose: 12,000 described species (estimate number of species believed to exceed 94,000) Genital opening covered by a single shield
Cohort (or infraorder)	<i>Gamasina</i> Kramer, 1881	Comprises most of the described species of Mesostigmata and most families of vertebrate parasites
Subcohort (or hyporder)	<i>Dermanyssiae</i> (or Dermanyssina) Evans & Till, 1979	Female sperm access system opening by pair of small pores (solenostomes) in region of coxae II–IV. Male chelicerae with a spermatodactyl
Superfamily	<i>Dermanyssoidea</i> Kolenati, 1859	Comprises 17 families Large and diverse assemblage of free-living and parasitic taxa Many classification schemes proposed in past years for this complex group
Family	<i>Laelapidae</i> Berlese, 1892 ^a	Comprises 90 genera, more than 1300 species
Family	<i>Dermanyssidae</i> Kolenati, 1859	Comprises 2 genera, 26 species

^aAccording to Trach and Joharchi (2018), the family Laelapidae comprises 146 genera and over 1500 species.

Laelapidae—The family Laelapidae is a cosmopolitan heterogeneous group including thousands of species (Table 1) and showing the full gamut of life-history strategies and associations: they are free-living predators in soil (e.g., some *Androlaelaps* spp.), as well as nidicolous commensal, facultative or obligate ectoparasites in nests and colonies of vertebrates and insects while the possible endoparasitic association to marsupial mammals has not been fully investigated (e.g., Radovsky, 1985; Gettinger et al., 2005; Dowling and Oconnor, 2010; Lindquist et al., 2009b). Mites of the subfamily Laelapinae are the most common ectoparasites of small rodents and frequently found on the rodents' body or in their nests (e.g., Strandtmann and Wharton, 1958; Gettinger et al., 2005; Lindquist et al., 2009b; Mařán and Fenřa, 2010; Kaminskienė et al., 2017, 2020). Several species (e.g., members of the genera *Haemolaelaps*, *Echinolaelaps*, and *Laelaps*) are blood-feeding parasites of rodents and are found worldwide; only a few species can occasionally bite humans (Wall and Shearer, 2001).

Dermanyssidae—The family Dermanyssidae is a much more uniform group; they are all obligate hematophagous ectoparasites of primarily birds, and rodents, and with less extent other mammals, including humans (Lindquist et al., 2009b).

Taxonomy and identification

Acarine systematics are highly controversial and systematic problems also occur with the lower categories. Several times the same taxonomic name is used by different authors for grouping different taxa or with different meanings. An extreme example, at the highest levels, is that some authors consider the Acari a subclass, others a superorder of Arachnida (Lindquist et al., 2009a).

Even placement of a single mite in the proper suborder requires a trained scientist, slides-mounted species, a compound microscope (Dermanyssoidea are medium-sized mites, <1 mm in length), and identification keys. In this respect, keys to the Superorders, Orders, and Suborders of Acari can be found in Lindquist et al. (2009a).

Things get even more complicated with the lower levels. The taxonomy of the superfamily Dermanyssoidea has been in a perpetual state of flux since the late 19th century. Many classification schemes, often contradictory, have been proposed by different researchers, typically based more upon ecology and host associations than any character evidence. Sometimes even the taxonomic rank of the families is disputable: i.e., some acarologists considered some groups as subfamilies while others ranked them as separate families (Lindquist et al., 2009b).

Since identification keys of the Mesostigmata families (Lindquist et al., 2009b) are based on adults (normally females), it is crucial to be able to distinguish adults (males and females) and juveniles (see Life cycle, for details). Both reproductive and morphological criteria are used in the higher classification of the Mesostigmata. One major division is based on the method of insemination (podospermic or tocospermic, see "Reproduction and mating behavior", for details). Mites of the subcohort Dermanyssiae are all podospermic and characterized by the presence, in the females, of an insemination system (or sperm access system) opening by a pair of pores, by a male genital orifice in presternal position, and movable digit of male chelicera with spermatodactyl (Evans, 1992; Alberti and Coons, 1999). Among Dermanyssiae identifications of families and species is based on several diagnostic characters: ventral sclerotization of the female (e.g., sternal, genital or genito-ventral and anal shield or ventro-anal shields) (Fig. 1), chaetotaxy of the dorsum and venter that form a predictable pattern (Fig. 2A), chaetotaxy of the legs, presence of lyrifissures and pores on the dorsum, morphological diversity of the chelicerae (Fig. 2B–D), relative length of peritremes vs. coxal position.

Reliable species determinations require the preparation of slide-mounted species for microscopic examination and the assistance of an acarologist with the proper background and who has access to the appropriate taxonomic literature. In fact, there are no comprehensive publications including species identification keys and the few catalogs or reviews available do not cover the whole species comprised in the families Laelapidae and/or Dermanyssidae. Quite often, keys available in taxonomic articles refer only to species from certain geographical areas (e.g., Moss, 1968, 1978; Mařán and Fenřa, 2010; Mařán et al., 2014; Vinarski and Korralo-Vinarskaya, 2016; Kaminskienė et al., 2017). Thus, specific identification is challenging due to the lack of (detailed) descriptions, and because different dermanysoid species can share the same environment and/or host, and because the use of taxonomic identification keys—to differentiate between them—requires expertise that is no longer widely available. This is even more critical for the family Laelapidae since mites infesting small mammals have been less intensely studied. Finally, the reliability of some of these diagnostic characters seems to be doubtful or not stable enough and many intraspecific variations have been reported, both in the family Laelapidae and Dermanyssidae (e.g., Roy and Chauve, 2007; Roy et al., 2010a; Lareschi and Galliari, 2014; Silva-de la Fuente et al., 2020). Thus, the presence of cryptic¹ species and/or species complex have been hypothesized and, in some cases, confirmed by genetic studies (Gettinger and Owen, 2000; Roy et al., 2009a,b, 2010a; Roy and Buronfosse, 2011; Engelbrecht et al., 2014; Lareschi and Galliari, 2014; Silva-de la Fuente et al., 2020).

Compared to the family Laelapidae, which includes a huge amount of species, the much smaller family of Dermanyssidae includes only two genera, *Dermanyssus* and *Liponyssoides* (Evans and Till, 1962; Moss, 1967, 1968, 1978; Roy and Chauve, 2007, 2010; Lindquist et al., 2009b; Beaulieu et al., 2011). The extremely elongated second cheliceral article of females and the highly reduced digits of the chela (with stylet-like chelicera (Fig. 2C)) are diagnostic for this latter family (see Di Palma et al., 2012a for details and illustrations).

¹Cryptic species are species that do not possess any morphological divergence with their closest sister(s) so they may not be distinguished from each other based on morphology alone. They are usually the result of a recent speciation event.

Fig. 1 Light microscopy (LM). Examples of several ventral sclerotizations in females belonging to different families of Dermanyssidae (A) Macronyssidae, (B) Pachylaelapidae, (C) Macrochelidae, (D) Laelapidae. Note: different shape and dimension of the genital (epyginal) shields (gs) and of the sternal shields (st) in all pictures, presence of a genito-ventral shield (gvs) in (B), ventro-anal (vas) shield in (C), and anal shields (as) of different shape in (A) and (D). All these characters are diagnostic for the identification of the families. Scale bar: 50 μ m.

Dermanyssus species morphologically fall into two groups: (i) those possessing a soft body adapted for sporadic and large engorgement with reduced shielding and slender legs, and (ii) those possessing a compact, more heavily sclerotized body with shorter, stouter legs. Species possessing the soft-body type are the most common and most of them are nearly indistinguishable from each other and constitute the *gallinae*-group (Roy et al., 2009a).

Biology and ecology

Reproduction and mating behavior

Among the different reproductive modes, haplodiploidy is a widespread phenomenon in mites. In haplodiploidy, males are haploid and females are diploid and it can be caused by a number of different underlying genetic systems. One of the most common is arrhenotoky: a type of parthenogenesis where haploid males are produced from unfertilized eggs, whereas diploid females result from fertilized eggs.

Arrhenotoky appears to be quite frequent among the subcohort Dermanyssidae (or Dermanyssina) in that it is the predominant form of reproduction in several families of the subcohort (e.g., Macrochelidae, Dermanyssidae, Macronyssidae) and for at least some species in the laelapid family (e.g., Furman, 1966; Mitchell, 1968; Oliver Jr, 1965, 1971; De Jong et al., 1981; Evans, 1992). In such cases, like *Dermanyssus gallinae* (Dermanyssidae), females lay haploid (unfertilized) and diploid (fertilized) eggs which

Fig. 2 (A) *Dermanyssus gallinae*, SEM. Female dorsal shield (ds) with a characteristic layout of the setae. (B) An example of chelicerae with robust chelae (arrows) in the family Laelapidae (LM). (C) *Dermanyssus gallinae*, LM. Female chelicerae modified in elongated stylets (arrowheads), this is a character diagnostic for the family. (D) *Dermanyssus gallinae*, LM. develop into males and females, respectively (Oliver Jr., 1966; Hutcheson and Oliver Jr., 1988). However, the Dermanyssidae contain diplo-diploid (both males and females derived from fertilized eggs) and pseudoarrhenotokous (males and females arise from fertilized eggs, but males eliminate the paternal genome) groups as well. Phylogenetic studies suggest that arrhenotoky should be derived from pseudoarrhenotoky (De Jong et al., 1981; Cruickshank and Thomas, 1999). A switch from pseudoarrhenotoky to arrhenotoky confers the advantage to a female of being able to produce offspring without mating (facultative asexuality). Indeed, females lay unfertilized eggs that produce males who can mate with their mothers. This means that, in arrhenotokous species, a new habitat patch can be colonized by a single un-inseminated female who can parthenogenetically produce males with which to mate, thus getting new females for her sons to mate with. In this way, one female can found a new colony. This is likely to be of particular importance in parasites (like Laelapidae and Dermanyssidae), in which the new habitat patch represents an uninfected host (Cruickshank and Thomas, 1999).

Regarding mating behavior, among Mesostigmata only direct sperm transfer occurs: the male introduces the sperm in the female (Alberti and Coons, 1999 and references therein). In particular, in the Dermanyssidae the males present chelicerae modified as gonopods and equipped with a sperm transfer appendage, called spermatodactyl (Fig. 2D), provided with a canal (Di Palma et al., 2006, 2009, 2013a, and references therein). Males use the spermatodactyl to inject the sperm material into a pair of female's insemination pores (sperm induction pores, solenostomes) usually located close to the base of legs II–IV. Thus, this mode of direct sperm transfer is termed “podospermy” (Alberti and Coons, 1999; Krantz, 2009c, and references therein). The insemination pores lead to a complex insemination system where sperm is stored and transferred to the ovary. This insemination system was first described by Michael (1892) and proved to have systematic relevance for families and species identification (Evans, 1992; Krantz, 2009c). Currently, two basic types of sperm access system are known in the Dermanyssidae: a laelapid and a phytoseid-type with several variations (Alberti and Coons, 1999 and references therein; Di Palma and Alberti, 2001; Di Palma et al., 2012b, 2013b,

2017); the families Laelapidae and Dermanyssidae both present insemination system of the laelapid-type (Evans, 1992; Alberti and Coons, 1999 and references therein).

In Dermanyssidae, mating occurs in the venter to venter position (more frequently) or ventro-laterally with the male laying between the legs of the female and using his second pair of legs to hold the fourth pair of legs of the female. The male produces, from his genital orifice, a sperm package (the spermatophore), then he collects the spermatophore with the help of the chelicerae and flexing the gnathosoma (Alberti and Coons, 1999; Krantz, 2009c and references therein). The sperm fluid passes from the spermatheca into the spermatodactyl canal whose tip is inserted into the female insemination pore so that sperm fluid is injected into the insemination system (Alberti and Coons, 1999; Krantz, 2009c; Di Palma et al., 2006, 2009, 2013a).

Life cycle

As in all arthropods, postembryonic development of Acari is characterized by molts that divide the life cycle into a number of instars. Ontogenetic development in the Mesostigmata includes egg, larva, protonymph, deutonymph, and adult male and female (Evans, 1992; Walter and Krantz, 2009). The adoption of a parasitic mode of life by members of the superfamily Dermanyssoidea has been accompanied by a variety of morphological and life-cycle modifications (Walter and Krantz, 2009).

Laelapidae and Dermanyssidae are normally oviparous with stages in the life cycle consisting of egg, nonfeeding larva, feeding protonymph, deutonymph, and adults (Furman, 1966; Mitchell, 1968; Maurer and Baumgärtner, 1992; Walter and Krantz, 2009). Anyway, in many laelapines the egg and even the larval stage may be suppressed, with females giving birth to larvae or even protonymphs (Radovsky, 1969, 1994; Mitchell, 1968). Usually, eggs are produced singly (Fig. 3A) and not in a cluster and not on

Fig. 3 *Dermanyssus gallinae*, SEM. (A) An egg deposited singly. (B) Larva with three pair of legs and no evident shields. (C) Nymph with four pair of legs and a reduced genital shield (arrowhead) without genital opening. (D) Male with an elongated holovenral shield (hs) carrying the genital opening (arrow). Scale bar: 50 μ m (A); 100 μ m (B); 150 μ m (C and D).

the host. In obligate parasites (as in *Dermanyssus* spp.), eggs are laid shortly after feeding and a blood meal is required for each gonotrophic cycle, and oviposition is sustained until all blood ingested is digested (Tucci et al., 2008).

Larvae are hexapod (Fig. 3B) lacking the fourth pair of legs, while the nymphal and adult stages are all octopod. Each stage has distinct setal and idiosomal shielding patterns. The larva typically possesses very little, if any, shielding (Fig. 3B), and reduced setation. Each successive molt increases both shielding (Fig. 3C and D) and setation until the full complement of each is reached at the adult stage (Dowling, 2006; Walter and Krantz, 2009). The sexes in the Dermanyssoidea are readily recognized by the relative shape of the shield covering the genital orifice and the shape and position of the genital opening (Figs. 3D and 4). Secondary sexual characters are represented by the spermatodactyl (Fig. 2D) on the male movable digit (see [Reproduction and mating behavior](#)) and hypertrophy of certain setae on the male legs (Evans, 1992).

The average life developmental time in several species of Laelapidae is 10 days and even less for some Dermanyssidae (Furman, 1966; Mitchell, 1968; Hutcheson and Oliver Jr., 1988; Evans, 1992; Walter and Krantz, 2009). For example, *D. gallinae* can complete the life cycle in 7 days with warm temperatures (between 25 and 37 °C) (Maurer and Baumgärtner, 1992; Chauve, 1998), but takes considerably longer (16.8 days) during colder periods (lowest 20 °C) proving that it is a poikilothermic organism whose population ecology is very much influenced by the temperature. Nevertheless, this species can develop and reproduce in a wide range of temperatures (Tucci et al., 2008) and it seems that higher temperatures (up to 35 °C) are less restrictive than lower ones.

Another important adaptation of parasitic species is their ability to survive adverse environmental conditions (Kirkwood, 1963; Nordenfors et al., 1999; Chauve, 1998): some species can survive for 9 weeks (i.e., *Liponyssoides sanguineus* Hirst) (Mullen and Oconnor, 2019) without a blood meal or as long as 55 weeks (i.e., 13 months) (i.e., *D. gallinae*) (Pavličević et al., 2007). The ability of parasitic mites to withstand starvation is of high practical importance.

Feeding habit

Parasitic genera of the dermanyssoid mites can be permanent parasites (i.e., the mite remains on the host throughout its life cycle) or nidicolous (i.e., the mite spends part of its life cycle in the nest, roost, or another dwelling but it is also found on the host). Some species have mixed feeding behavior that includes blood-feeding as well as predation and scavenging (Radovsky, 1994). Since the chelicerae of male parasitic dermanyssoids are modified for sperm-transfer (see [Reproduction and mating behavior](#)) their capacity in feeding must be greatly reduced or even lost entirely; indeed, males usually feed very occasionally (Radovsky, 1969, 1994).

For most laelapids associated with mammals, it is unknown whether they are nidicolous, facultative, or obligate parasites. Species of some genera (e.g., *Androlaelaps*, *Laelaps*) are known to feed facultatively on nesting rodents but apparently cannot penetrate with their chelicerae the unbroken skin of their host suggesting they usually feed at an abraded area made by other ectoparasites or other means (Mitchell, 1968). Perhaps blood is oozing from a small scratch on the rodent incurred during its activities, or a small blood droplet is forming where a flea has just withdrawn its mouthparts thus, mites, luckily oriented toward the blood by odor, feed to repletion (Mitchell, 1968). For other species cannibalistic and predaceous tendencies have been observed (e.g., genera *Haemolaelaps* and *Laelaps*) (Furman, 1966) while nidicolous commensal species feed on a variety of substances,

Fig. 4 *Dermanyssus gallinae*, LM showing different arrangement of the ventral shields in male and female. (A) Ventral view of a male: see the long holovenral shield (hs) with the anterior genital opening (arrow). (B) Ventral view of a female: see the small sternal (st) shield, the long genital shield (gs) and the small anal shield (as). Scale bar: 100 µm.

including small arthropods and flea feces in the nest and ectoparasites on the host itself (Krantz, 2009b). A confirmation is represented by some laelapid species previously considered parasitic and even suspected of causing dermatitis or skin irritations in humans, which have been proved to be mostly predaceous free-living or saprophagous and with loose connections to nest habitats and without any sanitary significance (Krantz, 2009b; Halliday, 2011). An example is a species very common in nests of wild birds (i.e., *Androlaelaps casalis* (Berlese, 1887)) sometimes regarded as parasitic; however, there is evidence that it is actually a predator that can feed on parasites of birds (Lesna et al., 2009). The genus *Androlaelaps* Berlese, 1903 is cosmopolitan and includes species with a variety of feeding modes (Radovsky, 1985; Martins-Hatano et al., 2011) making crucial species identification. These observations are consistent with the morphology of the chelicerae of these species which have dentate opposable digits (Fig. 2B) typical of predatory Laelapidae, not the elongate edentate digits that are commonly found in true parasites (Radovsky, 1985, 1994). Thus, the family Laelapidae shows a gradation from polyphagous to parasitic feeding with variations in the adaptation of the chelicerae from stout chelate-dentate chelicerae, more adapted for grasping and tearing the cuticle of small prey, to chelicerae modified to penetrate unbroken skin (starting with species that make crater-like holes in the skin of suckling rodents) (Radovsky, 1969).

Species of Laelapidae parasitic of vertebrates can live permanently or temporarily on their hosts (e.g., Mařán and Fenřa, 2010; Kaminskienė et al., 2017, 2020 and references therein). Among the genus *Laelaps*, the spiny rat mite (*Laelaps echidninus*) is hematophagous or tissue fluid-feeding; it is doubtful if its chelicerae are able to pierce intact skin or instead assist the mite in feeding on blood or serous exudates from abraded skin. It lives primarily in host bedding or nesting materials, moving onto the host at night to feed (Pratt, 1963; Lareschi and González-Acuña, 2010; Mullen and Oconnor, 2019).

In dermanyssoid groups, specialization of the chelicerae for skin-penetration has highly evolved in the family Dermanyssidae. The elongated second segment of the chelicerae (Fig. 2C) with highly reduced stylet-like chelae at their tips (Phillis III, 2006) function for piercing host tissue and sucking blood (Fig. 5). Thus, dermanyssids are typical blood-sucking nest parasites with a pronounced engorgement capacity and an ability to withstand starvation for months. They usually spend most of the time in the nest when not feeding; however, some species remain on the host for extended periods of time (Radovsky, 1994). Each stage (larvae excluded, since they do not feed) needs to feed before develop into the following one.

Nymphs and adults of *Liponyssoides sanguineus* (Hirst) (Dermanyssidae) are bloodsucking and feed for short periods of 1–2 h on the host while spending most of the time in the nesting materials, along the walls of infested premises, and especially in warmer areas of buildings. Nymphs generally take a single blood meal, adults move onto and off the host to take several blood meals (Fischer and Walton, 2014; Mullen and Oconnor, 2019; Ereemeeva and Muniz-Rodriguez, 2020).

Fig. 5 *Dermanyssus gallinae*, SEM. (A) Lateral view of a female with the stylets (arrow) protracted. (B–D) Detail of the stylet-like chelicerae modified to pierce the host tissue. In (B) the stylets are coupled (see the longitudinal line (arrow)) while in (C) they are separated with the evident concave surface (arrowheads). In (D) remembrance of the chelae (arrowheads) are visible at the tip of the stylets. Scale bar: 150 μ m (A); 30 μ m (B); 25 μ m (C); 10 μ m (D).

Fig. 6 Clusters of *Dermanyssus gallinae* (arrow) hidden in the structures of laying hen cages.

Dermanyssus gallinae is blood-sucking and feeds every 2–4 days, mainly at night (although not exclusively, Nakamae et al., 1997) and normally stays on the birds approximately 30–60 min before returning to hide (Fig. 6) (Kirkwood, 1963; Chauve, 1998; Maurer et al., 1988). The mite prefers areas of the host's body with few feathers, where the skin is thin and the veins are superficial, such as the neck, back, and under the wing (Giangaspero et al., 2016).

Unlike ixodid ticks, dermanysids are characterized by multiple brief acts of blood-sucking, each accompanied by salivation. This seems supported by the dynamics of the secretory activity and in the non-simultaneous release of secretion from different cells of the salivary glands (Amosova and Stanyukovich, 2008).

Host range, host location and distribution

Mammalian ectoparasites can be monoxenous (occurring on a single species of host), oligoxenous (occurring on a few host species), and polyxenous (capable of infesting a broad array of host taxa). Polyxenous ectoparasites may be limited to host species that are closely related phylogenetically or may parasitize unrelated hosts that share ecological or behavioral similarities.

Regarding laelapid species obligate hematophagous of small mammals, it is under discussion whether there is a single polixenous species that parasites a variety of hosts, or whether there are cryptic species highly host-specific. Recent studies strongly indicate that they are primarily monoxenous (e.g., Gettinger, 1992; Martins-Hatano et al., 2002; Lareschi and Velazco, 2013) and when mites, initially assigned at the same species, infest more than one host species, an examination of the morphological variation within and among mite specimens support the hypothesis that mites infesting different hosts are reproductively isolated populations or species complex (Gettinger, 1992; Gettinger et al., 2011; Nava and Lareschi, 2012; Lareschi et al., 2013; Lareschi and Galliari, 2014). Host switching of mites among rodents has probably taken place, followed by speciation (Lareschi et al., 2013; Lareschi and Galliari, 2014; Silva-de la Fuente et al., 2020). Since some laelapids are vectors of pathogens, these processes of the new host colonization are also important from an epidemiological point of view.

The spiny rat mite, *L. echidninus*, and the smaller species, *Laelaps nuttalli* Hirst, 1915, are cosmopolitan ectoparasites. *Laelaps echidninus* is associated primarily with murid synanthropic rodents like the black rat (*Rattus rattus* Linnaeus 1758) and the Norway rat (*Rattus norvegicus* Berkenhout 1769). Moreover, it has been detected on Sigmodon, on the house mouse *Mus musculus* Linnaeus, 1758, and rarely on laboratory rodents (Pratt, 1963; Lareschi and González-Acuña, 2010; Mullen and O'Connor, 2019). *Laelaps nuttalli* is commonly found on commensal and wild *Rattus* species, while both (*L. echidninus* and *L. nuttalli*) can occasionally bite humans (Mullen and O'Connor, 2019).

Members of the family Dermanyssidae are primarily parasitic on birds, but contains a few species readily found on rodents. Rodent associated dermanysids are in the genus *Liponyssoides*, while species in the genus *Dermanyssus* are primarily parasites of birds; occasionally they have been collected from rodents and other mammals (Moss, 1967, 1968, 1978; Radovsky, 1985; Dowling, 2006; Lindquist et al., 2009b; Mullen and O'Connor, 2019).

Liponyssoides sanguineus, has been collected from many species of mammals throughout the world. The common house mouse, *Mus musculus*, is the preferred host, but this mite occurs also on peridomestic rats (*R. norvegicus* and *R. rattus*), diverse laboratory rodents, and rodents sold in pet stores. It readily attacks human beings as well (Fischer and Walton, 2014; Mullen and O'Connor, 2019; Ereemeeva and Muniz-Rodriguez, 2020).

Dermanyssus species show a rather low host-specificity with multiple host associations and a rather wide geographic distribution (Moss, 1978). For example, *Dermanyssus gallinae* is largely considered an avian-specific ectoparasite of farmed birds (e.g., chickens, turkeys, and ducks), as well as wild and synanthropic birds (e.g., pigeons, sparrows, starlings, and doves). However, it can occasionally feed on a range of mammals, such as cats (Guin, 2005; Di Palma et al., 2018), dogs (Ramsay et al., 1975; DeClerq

and Nachtegaele, 1993; Friesen et al., 2011), gerbils (Lucky et al., 2001), other rodents (Allymehr et al., 2012; Kowal et al., 2014), goat (Dorny et al., 1994), horses (Mignon and Losson, 2008), and humans (reviewed by Cafiero et al., 2019).

However, studies in the last decade have shown that most of the *Dermanyssus* species actually have more restricted host ranges than first believed (Roy et al., 2009b). In particular, *D. gallinae* might not be the only *Dermanyssus* parasitizing laying hens but that some other closely related species might often have been confused with this species (Roy and Chauve, 2007). Recent research based on morphological and molecular data (Roy et al., 2009a, 2010b; Roy and Buronfosse, 2011) has shown that *D. gallinae* is actually a species complex including at least two cryptic species. In particular, *D. gallinae* s. str. Appears to be the only pest in poultry houses, as well as on other bird species except pigeons, while *D. gallinae* special lineage L1 is restricted to pigeons only.

In general, blood-feeding ectoparasites utilize a variety of cues such as body heat, CO₂, and host-specific kairomones to locate their host. Regarding the ability of laelapid parasites to locate the host, some studies (Mitchell, 1968) highlighted the combination of responses toward carbon dioxide and blood as an important advantage for a nest-dwelling mite in actively seeking suitable hosts. Investigations on the host-searching process in dermanyssids have shown that mite-related cues (aggregation pheromones) and host-related cues (kairomones) mediate the behavior of the poultry mite (Koenraadt and Dicke, 2010) while foreleg tarsal sense organs are involved in stimuli perceiving (Soler Cruz et al., 2005). A gradual increase of CO₂ concentration, heat, and vibrations are powerful activating stimulus (Kilpinen, 2001, 2005) guiding mites toward the host thanks to the heat transmitted through the substrate or the exhaled air (as an indication that a potential host is near). After the mites have moved close to the potential host, recognition may be facilitated by skin lipids of birds, which are known to act as feeding stimulants to poultry red mites (Zeman, 1988). Anyway, CO₂ can elicit contrast behavior: mites “freeze” (i.e., they become motionless) in response to a quick increase of CO₂ when in light conditions (probably as a defensive strategy to avoid being eaten by the host) (Kilpinen, 2005). Thus, responses of mites toward CO₂ are likely to be dose and context-dependent. After the blood meal, *D. gallinae* forms aggregations of mixed developmental stages and thigmokinesis (i.e., increased locomotion in response to changes in contact with the immediate physical environment), and pheromones are thought to play a role in this (Entrekin and Oliver Jr, 1982; Koenraadt and Dicke, 2010). However, as nests are discontinuous and temporary microhabitats, an important adaptation of mite parasites involves the use of the host to disperse (Martins-Hatano et al., 2011).

Among laelapine nest mites, the female is usually the dispersal stage and most often found on the host, while males and immatures are presumed to be restricted to the nest of the host. In this way, dispersion is primarily vertical, between hosts of the same species (parents and young) occupying the same nest. The same happens with dermanyssids with females representing the dispersal stage most often collected on the host (Radovsky, 1985, 1994). Moreover, many families of Mesostigmata, including Laelapidae and Dermanyssidae, have established close phoretic relationships with other arthropods (Krantz, 2009b). Examples of phoretic behaviors on insects by *D. gallinae* have been reported twice (Flechtmann and Baggio, 1993; Pavlović et al., 2016). In this way, arthropods can contribute to mite distribution in the near vicinity, including houses and farms.

Anyway, there are parasite species whose presence is strongly related to human activities (i.e., *D. gallinae*). In this case, the most important aspect for their distribution, at least in Europe, has become trade flows (and not wild bird) that seem to be the routes that are the most often used by mites to disseminate. Mites use cages, birds, personnel that are carried by trucks during transfer as a spreading mean at high geographical scales (dozens to hundreds of kilometers) (Øines and Brännström, 2011; Roy and Buronfosse, 2011; Marangi et al., 2014).

Moreover, recent morphological studies explained the previously observed ability of some dermanyssoids (e.g., *D. gallinae*) to climb upwards on slippery surfaces as well as on a wide range of material, in the “off-host” environments (Mul et al., 2016), thanks to adaptations on the distal region of the legs (Di Palma and Mul, 2019). Such adaptations would have initially evolved in “wild-living” but would also prove beneficial for movement within poultry houses and thus explaining the possible active colonization of different facilities using the ventilation systems, wall fans, wall inlets, and air chimneys (Mul et al., 2009).

Medical and veterinary importance

The sanitary interest of Laelapidae and Dermanyssidae species stands on both their direct damage to the host (mostly related to the hematophagy) or indirect harmful effect (acting as vectors of pathogens) on their hosts. Direct damage can range from skin irritation to different degrees of blood deprivation. The indirect damage is related to their ability (thanks to the feeding behavior) to transmit a multitude of pathogens to animals and/or humans.

As to the latter effect, it should be underlined that simple detection of a vector-borne agent in an ectoparasite does not demonstrate vector competence. In fact, mites could acquire pathogens during the blood meals but might be unable to transmit them; on the other hand, not all parasitic dermanyssoid mites feed exclusively on blood but some could acquire pathogens by eating other ectoparasites such as fleas and lice. In addition, some bacterial agents (e.g., *Wolbachia* spp. and *Spiroplasma* spp.) are often endosymbionts of arthropods, and detection of these organisms might be misleading (Reeves et al., 2006; De Luna et al., 2009).

Some dermanyssoids are proven or suspected to play a role as vector and/or reservoir for pathogens of birds, reptiles, and mammals, including humans (e.g., Kocianová et al., 1993; Kocianová, 1989, 1993; Valiente Moro et al., 2005; Reeves et al., 2006; Mišková et al., 2015; Radzijejskaja et al., 2018); however, not conclusive data are available.

The medical and veterinary interest in the family Laelapidae is mainly due to the intimate association of some species with commensal rodents (see the “Biology and Ecology” section). Although some laelapid species are reported as causing occasional discomfort to humans (Mullen and Oconnor, 2019), Maaz et al. (2018) refer that such reports are very rare and mostly doubtful.

Indeed, most authors consider the spiny rat mite, *L. echidninus*, as the only significant laelapid species of sanitary interest. Although rarely, its feeding causes discernible lesions and injury to the footpads of suckling mice has been reported. However, the most important relevance of the spiny rat mite *L. echidninus* is due to the fact that it is capable of biologically transmitting disease agents among rodents (Table 2), such as the murine typhus (a worldwide rickettsial illness of commensal rats) and *Hepatozoon muris* (a blood protozoan of rats) (Mullen and Oconnor, 2019). Moreover, Junin virus, which causes Argentinian hemorrhagic fever, has been isolated from *L. echidninus* and associated rodent hosts in South America (Parodi et al., 1959) while, according to experimental studies, *L. echidninus* can transmit tularemia (a rabbit fever, caused by the zoonotic bacteria *Francisella tularensis*) (Strandtmann and Wharton, 1958). Anyway, the spiny rat mite’s role as a potential vector of human pathogens remains uncertain (Mullen and Oconnor, 2019).

Other rodent associated laelapid mites (*Haemolaelaps glasgowi* (Ewing), and *Laelaps cynognathus*), may have a role in the maintenance and transmitting Hantaan virus (the causative agent of Korean hemorrhagic fever) based on data reporting naturally infected mites and their ability to transmit the virus by bite to laboratory mice and, transovarially, to their offspring (Yu and Tesh, 2014). These findings are of particular interest since it is generally believed that the hantaviruses do not have an arthropod transmission cycle and that they are transmitted to mammals (rodents, insectivores, bats, and humans) by inhalation of aerosols of infected animal excreta or by bite. Moreover, recently, Kuo et al. (2020) and references therein highlighted the presence of spotted fever group (SFG) rickettsiae in hematophagous *Laelaps* mites, particularly in species closely associated with synanthropic rodents (i.e., *L. nuttalli* and *L. echidninus*). This calls for further investigation on the competence of these mites in transmitting rickettsiae. Finally, Alonso et al. (2020), in their survey, remark that ectoparasite-borne infectious diseases have been emerging or re-emerging throughout the world in the last years and their incidence is on the rise. Thus, considering that Norway rat is the most common vertebrate pest species in animal production systems and that it is a reservoir for several important zoonotic diseases, much attention should be paid to its parasitic fauna (e.g., Laelapidae) with potential sanitary importance and global geographical distribution. Attention should be also paid to other commensal rodents, such as house mice, *M. musculus*, or black rats, living

inside buildings, and wild rodents who harbor many zoonotic agents as well. In fact, the population density of these “peridomestic” rodents is even higher in urban than rural regions, due to a prolonged breeding season and better winter survival, and there are chances that they transmit diseases to domestic animals, mainly via vectors, turning them in an additional reservoir for human exposure (Zavala-Castro et al., 2009).

Regarding dermanyssid mites, the veterinary and medical concern of the genera *Liponyssoides* and *Dermanyssus* is better supported. Among the genus *Liponyssoides*, the house mouse mite *Liponyssoides sanguineus*, a cosmopolitan bloodsucking ectoparasite of synanthropic rodents, is very important as a vector of *Rickettsia akari*, the agent of the zoonotic rickettsialpox (Huebner et al., 1946; Ereemeeva and Muniz-Rodriguez, 2020; Szakacs et al., 2020 and references therein). Rickettsialpox occurs primarily in urban areas in crowded living quarters infested with the house mouse, which serves as the major reservoir. Despite being considered as a mild, self-limited zoonotic febrile illness, there is increased interest in rickettsialpox due to its clinical similarity to bioterrorism-associated diseases such as anthrax and smallpox. The transovarial and trans-stadial transmission of this rickettsia in *L. sanguineus* has also been demonstrated (see Ereemeeva and Muniz-Rodriguez, 2020). Moreover, *L. sanguineus* has been reported to transmit tularemia once (Strandtmann and Wharton, 1958) (Table 2). Among the genus *Dermanyssus* the species of greatest interest is *Dermanyssus gallinae*, also called the poultry red mite (PRM); this species deserves a more detailed discussion due to its serious economic consequences on animal welfare as well as, although marginally, to its interest on human health. As above mentioned, it is mostly considered an avian-specific ectoparasite of mostly farmed birds and among those, it is significantly related to chicken industries and a major threat to the laying hen industry, worldwide, particularly in Europe where *D. gallinae* infestation rates vary from 60% to 90% (Mul, 2017; Waap et al., 2019).

The sanitary and economic interest of *D. gallinae* is mainly related to its hematophagous behavior. As said, all legged stages, except larvae, feed on blood. While males suck blood only occasionally, one female can engorge about 200 micrograms of blood. Since the infestation level is usually high (up to 500,000 mites/head in heavily infested laying hens), hematopoiesis is insufficient to compensate for blood loss, and animals present marked anemia that is more pronounced in young subjects (Cosoroaba, 2001; Wojcik et al., 2000). Moreover, mites are responsible for amplified stress (feather-pecking, increased self-grooming, and cannibalism) (Kilpinen, 2005; Mul et al., 2009).

The consequences are a negative impact on weight gain, conversion index, and egg quality failure (due to blood spots and shell thinning) and production (up to 20% of laying reduction) (reviewed by Sparagano et al., 2014; Sparagano, 2020).

The sanitary and economic impact of *D. gallinae* in the poultry system is also related to its role as a vector of several pathogens. As shown in Table 2, several bacteria and viruses are associated with PRM; however, more robust scientific evidence of transmission has been documented only for some *Salmonella* species. Although for several pathogens the real vectorial competence of *D. gallinae* remains unconfirmed (Valiente Moro et al., 2005, 2009; Circella et al., 2011; Chu et al., 2015) its potential should not be underestimated also bearing in mind that heavy infestations are reported to suppress antibody production or reduce antibody titers to some viral vaccines by the host (Sparagano et al., 2014; Sparagano, 2020; Pugliese et al., 2019).

In non-avian hosts (e.g., dogs, cats, horse), attacks document from severe, mild, to absent skin lesions (DeClerq and Nachtegaele, 1993; Guin, 2005; Mignon and Losson, 2008; Friesen et al., 2011; Di Palma et al., 2018) and an immunological reaction in experimentally infested dogs have been described (Martins et al., 2020).

As to humans, attacks can occur in the poultry farm setting when the PRM infestation level is high and farmers, employees, or visitors are not properly protected (thus proposed as “occupational disease”), as well as in the urban context when the nests built close to residential buildings by synanthropic birds (mostly pigeons) are abandoned and hungry mites enter houses, residences, public buildings, hospitals, etc. through crevices and cracks around windows and doors, or via ventilation ducts and air-conditioning systems (Fig. 7) and attack humans (Cafiero et al., 2019; Sargison et al., 2020 for references). The symptoms of the infestation by *D. gallinae* in humans (often recurrent) range from pruritic dermatitis, erythematous rashes, small papules and blisters, urticarial plaques, and erythema—with consequent histological changes—and are mostly described on arms, hands, chest, legs (see Cafiero et al., 2019) (Fig. 7).

The importance of this mite species in public health also stems from their role as reservoirs/vectors of zoonotic pathogens (see Table 2). Though human infestations are frequently associated with adventitious feeding, the risk of transmitting arthropod-borne disease might be considered remarkable.

Finally, another important issue related to the medical and veterinary importance of these family mites is that the host switching phenomenon followed by speciation reported for both laelapid and dermanyssid species (see “Host specificity and distribution” section), which in turn could lead to the colonization of new natural and artificial biotopes by these species can have unpredictable consequences. In particular, considering that laelapid species can be associated with bats (e.g., Radovsky, 1966; Fain, 2001; Shaw, 2011) the emergence of important viral diseases associated with these mammals and possibly transmitted to humans may be a current and future worrying topic.

Prevention and control

Infestations and attacks of humans in public places or private houses by rodent and/or avian associated dermanysoid mites (e.g., *L. echidninus*, *L. nuttalli*, *L. sanguineus*, *D. gallinae*) are mainly accidental. Mites move from their hosts or from nests to human beings when the original hosts naturally leave the nest (this happens in birds when the chicks can fly) or are disturbed by treatments or restoring of the buildings. Prevention practices such as removing pigeon or other bird nests, erecting meshes to stop them from

Fig. 7 *Dermanyssus gallinae*. (A) Dermatitis on a human chest caused by mites migrating from an abandoned pigeons' nest (arrow) in an air-conditioning unit in a private office (B).

nesting (Cafiero et al., 2019) and targeted control measures against commensal rodents (mainly rats) are highly recommended. Site inspection is the crucial step which allows recognitions, for examples, of the *D. gallinae* origin (abandoned birds' nests on balconies, attics, eaves, windows and holes near the building) and their possible indoor hiding places such as heated spots (under bed covers, electrical devices, laptop computers, television and radio clocks, etc.).

Failure to eliminate commensal rodents in urban contexts or to prevent mite migration during pest treatments may result in repeated infestations or new infestations by their associated mites, even at sites distant from the original foci, and regard seriously marginalized population such homeless.

In case of suspected or confirmed episodes of dermatitis it is recommended the patients should shower extensively and wash their clothes at 60 °C; infested premises should be intensively vacuum cleaned and disinfested using pyrethroids, while textiles (curtains, carpets, cushions) should be steamed clean or washed at 60 °C (Cafiero et al., 2019).

More serious is the situation related to occupational dermanysiosis by *D. gallinae* in humans which is related to the poultry farm infestation and requires improvements in control strategies (see below). To avoid infestation, poultry workers must be covered by suitable protective clothing, before entering the facilities (Cafiero et al., 2019).

The veterinary interest is mostly related to Dermanyssidae and particularly to *D. gallinae*. The overall cost of *D. gallinae* to the poultry industry—roughly estimated at € 231 million per year for the EU egg industry, with similarly significant losses elsewhere (Sparagano et al., 2014; Van Emous, 2017; Sleeckx et al., 2019)—imposes strict control strategies. However, when established in a poultry farm, the control of *D. gallinae* is very challenging due to its high reproduction rate, long survival period (even in absence of the host), feeding and resting behavior, increasing resistance to commonly used acaricides (Sparagano et al., 2014; Sparagano, 2020 and references therein).

Basic practices as cleaning and hygiene facilities between flocks can greatly reduce *D. gallinae* numbers but are often underestimated as control practices, or too costly (as steam and heat treatments), and, in the mean time, these are unable alone to eradicate infestations.

To date, worldwide, control of the key pest of the poultry industry (the PRM) is dominated by the use of synthetic acaricides. Organophosphates, pyrethrin, pyrethroids are still commonly used; only a few products are licensed in the EU for use against *D. gallinae*, and not many new molecules are marketed by pharmaceutical companies. Recently, only a fluralaner-based product belonging to the isoxazolines group has been developed and commercialized (see Sparagano, 2020). Indeed, successful treatment is more and more hampered by the ability of *D. gallinae* to develop resistance to multiple acaricides, as well as product residues (Giangaspero et al., 2016). The recent planetary scandal related to the presence of residues of fipronil (an unlicensed molecule) in eggs, represents the tip of the iceberg, i.e., the continuous needs by farmers of new molecules to combat *D. gallinae* in laying hen farms.

Consequently, farmers call for urgent alternative control strategies. In this view, natural acaricide compound formulations against *D. gallinae* are becoming increasingly more accessible, such as spinosad-based, and neem-based products. Collaterally, desiccants (i.e., inert substances such as silica dusts, able to break down the mite's waxy surface layer) are now commonly used by farmers (Sparagano et al., 2014; Sparagano, 2020 and references therein).

In the meantime, plant-derived products (PDPs) and natural enemies are beginning to provide natural solutions to control *D. gallinae*. Essential oils, herbs or plant extracts have produced some promising results especially for their primarily fumigant action able to penetrate mite refugia (see "Biology and ecology" section) and their bio-efficacies such as ovicidal, repellent, antifeeding, and biocidal activities (Sparagano et al., 2014 and references therein; Tabari et al., 2017; Lee et al., 2019). Nevertheless, variable

efficacy (due to different plant varieties, parts, geographic location, seasonality, method of oil extraction, year of harvest, storage conditions, and components used in product formulation) is widely recognized as a restraint and an impediment to their use in the field and commercial development.

Biological control approaches using PRM predators seem to reduce the mite infestation and some predator species are now commercially available (e.g., *Cheyletus eruditus*, *Androlaelaps casalis*) and can be used in combination (Sparagano et al., 2014; Sparagano, 2020). They will not eradicate PRM but have the potential to allow an acceptable low-level infestation with no harm to poultry, product, environment, and people. Future areas of development which show promises are also represented by entomopathogenic fungi (e.g., *Aspergillus* spp., *Metarhizium* spp., *Beauveria bassiana*) that can penetrate the integument of arthropods and cause a delayed pathology and, thus, become widely disseminated and, potentially, eliminate large mite populations (Sparagano et al., 2014; Pritchard et al., 2015; Sparagano, 2020; De Olivera et al., 2020 and references therein). However, further research is urgently needed concerning their practical application in poultry farms.

In conclusion, despite recent technological innovations in the poultry industry and the level of productivity achieved in recent years, *D. gallinae* is still a worrying issue worldwide. It is important to underline that an acceptable control of *D. gallinae* in poultry systems would be possible only through Integrated Pest Management (IPM) strategies; however, IPM strategies—largely limited to basic biosecurity, synthetic acaricides, sanitation, and physically acting substances—remains under-utilised in the poultry industry compared to agricultural sector, such as horticulture. There is a long way still to achieve an highly effective and sustainable control of *D. gallinae*. In the meantime, the following simple considerations should be highlighted.

The application of any control methods must be based on the correct identification of the involved pests. Once identified, the control of the red mite infestations could be achieved by strict preventive and sanitary measures. The application of hygiene regulations (cleaning and hygiene facilities, farmer and technician awareness of the problem, an interruption between the production cycles and thorough disinfection before the arrival of new birds, careful checking of new animals) on poultry farms would prevent or limit the infestation.

Regular monitoring of the burden of poultry red mite on a farm is a critical point² and would allow prompt intervention to be taken as soon as the red mite population starts to increase (Oh et al., 2020).

Anti-resistance strategies imply selection of effective products against *D. gallinae*, safe for animals, humans, and the environment, the correct dose and low application frequency, use in empty houses between flocks.

The most promising approach for controlling *D. gallinae* would be via vaccination, which offers the advantages of prolonged effectiveness, freedom from chemical residues/environmental pollution, and a reduced risk of resistance.

Although improvements in mite in vitro rearing and in vivo testing (Bartley et al., 2012; Nunn et al., 2020), application of omics strategies (Price et al., 2019; Lima-Barbero et al., 2019a,b), and delivery methods (Price et al., 2019) are helping to facilitate progress in this field,³ much has still to be done to develop a commercially viable vaccine for *D. gallinae*.

²Traps (mimicking refuges for the fed mites), both industrially produced or simple homemade with cardboard, corrugated PVC, or pieces of knotted white cloth in cages or nearby and examined every few days or once a week (see Sparagano, 2020 for references) can be used, including, more recently, an automated mite counter (Mul et al., 2015; Mul, 2017; Mul et al., 2017).

³Recent experimental recombinant subunit vaccines have shown to induce mite mortality and importantly reduce mite oviposition (Price et al., 2019; Lima-Barbero et al., 2019a,b); and in the case of an autogenous vaccine, reduce the *D. gallinae* population in a field study (Bartley et al., 2017).

Introduction

Chigger mite is a general term that can refer to larval stages of mites that belong to three main families: i.e., Trombiculidae Ewing, 1944; Leeuwenhoeikiidae Womersley, 1944; and Walchiidae Ewing, 1946 (Acariformes: Trombidiformes). Of the above, Trombiculidae is of medical and veterinary importance, given that parasitic larvae, in general, have low specificity, being able to parasitize a plethora of hosts, including humans (Mendoza-Roldan et al., 2020a). Furthermore, some species of Trombiculidae mites have been pointed out as capable vectors of pathogens, some of which are of zoonotic concern (Ewing, 1944; Fischer and Walton, 2014; Jacinavicius et al., 2018). While the adult and nymphal stages predate on the eggs and juvenile stages of other arthropods, chigger larval stages are parasitic of animals, being distributed throughout the world. The most important species are in Europe *Neotrombicula autumnalis* (harvest mites) (Fig. 1), in the Americas *Eutrombicula alfreddugesi* (chiggers mites) (Fig. 2) and in Asia and Australia *Eutrombicula sarcina* (scrub itch mites) (Diaz, 2010; Parcell et al., 2013; Santibáñez et al., 2015). The pathogenic effect of trombiculids is mainly linked to the pruritic dermatitis they cause in animals and humans.

However, some of them (e.g., *Leptotrombidium akamushi* and *L. deliense*) may be also vectors of rickettsial disease scrub typhus, caused by *Orientia tsutsugamushi* (formerly known as *Rickettsia tsutsugamushi* and *R. orientalis*) in eastern and southeastern Asia, New Guinea and northern Australia (Stekolnikov, 2013; Chakraborty and Sarma, 2017; Elliott et al., 2019; Kumler et al., 2018). Other species such as *Neoschongastia americana* are important pests of turkeys in the southern States of North America and they may also attack many other bird species (Kunz et al., 1969).

Based on the peculiar parasitism of larvae, this instar bears a robust gnathosoma with strong, blade-like anteromedial-oriented chelicerae, which are surrounded by stout, segmented palps with a typical claw-shape into the penultimate (palpal tibia) and ciliated setae on the terminal segment (palpal tarsus) (Goff et al., 1982; Kumler et al., 2018). The respiration occurs transcutaneously and there are not stigmata or tracheae. On the dorsal idiosoma, it is possible to observe the scutum, which usually bears a pair of sensilla (trichobothria), which are setaceous in many genera and inflated in other (e.g., *Schoengastia*), with four ciliated setae at each corner of the scutum and a single anteromedian seta (paired in *Apolonia*) (Fig. 3). Body surfaces carry ciliated setae, which distribution, along with the morphological characteristics abovementioned, represents important features for the taxonomic classification of trombiculids (Goff et al., 1982). The body of nymphal and adult trombiculids are covered by dense pilose setae on legs, body and palps (they are also known as velvet mites) and bear stigmata at the base of the chelicerae (Jenkins, 1947; Moniuszko et al., 2017). When larvae penetrate into the host skin, using their chelicerae, they start feeding on the host and the saliva partially digest tissues forming a feeding tube (stylostome) (Shatrov and Felska, 2017). Moreover, chigger mites in general attach to the epidermis with their chelicerae feeding of the exudates produced (Fig. 4), whereas some genera of the Leeuwenhoeikiidae family may burrow in the subcutaneous tissue mainly of amphibians (Fig. 5) (Silva-De La Fuente et al., 2016). In both cases, chigger mites feed on exudates composed by epithelial cells and lymph, and rarely some hematic cells. Larvae feed through the stylostome, which represents an artificial duct and is similar in function to the cement produced by ticks during attachment to the host (Shatrov, 2009; Bullard et al., 2016).

After feeding for several days, larvae fall to the environment and enter a quiescent phase prior to molt to the protonymph, then through other two stages to adults with a typical figure-of-eight shape body (about 1 mm long). While in tropical regions trombiculid infestations of larvae occur throughout the year, in temperate areas they perpetuate during late summer or early autumns (thus the species name of *N. autumnalis*). Therefore, hatched larvae usually climb on the grass (to a height of 60–80 mm) attacking any host (e.g., sheep, cattle, dogs, humans) they come in contact with (Guarneri et al., 2017a,b; Moniuszko et al., 2017).

The biological cycle generally includes eggs, prelarva or deutovum, followed by larvae, three nymphal instars of which deutonymphs are active and protonymphs and tritonymphs are inactive, and finally adults. Inactive prelarvae eclode from the eggs, 6 days after being laid, and active parasitic larvae emerge, feeding on the host in about three to 5 days (more than 10 days in skin-dwelling Leeuwenhoeikiidae larvae). After engorgement, larvae detach and return to the environment where they go through

different active or inactive instars (inactive protonymph or nymphochrysalis, active deutonymphs which develop four pairs of legs, and inactive tritonymphs). Finally, nymphs molt to adults, completing the cycle in two to 12 months depending on the species and quiescent stages duration. Species that occur in temperate regions can complete up to three generations, whereas tropical ones have continuous cycles all year round (Servat et al., 2018; Lv et al., 2019). Given the medical and veterinary relevance, this chapter will provide a detailed focus on Trombiculidae chigger mites, highlighting the peculiar biology, ecology and control of the species of major public health importance.

Trombiculidae Ewing, 1944

Members of the Trombiculidae family are the true chigger mites, also known as harvest mites. Larvae are red, white or yellowish in color and approximately 150–300 μm in size. Mites of the families Leeuwenhoeikiidae and Trombiculidae share morphological and life cycle similarities. The main morphological difference is the segmentation of the legs. Trombiculidae have 7-7-7 or 7-6-6 leg segmentation (Fig. 6A), and Leeuwenhoeikiidae have 6-6-6 (Fig. 6B), except for the genus *Comatacarus* Ewing, 1942, which has 7-6-6 leg segmentation (Kolebinova, 1992). For most of the described species, only the larval stage is known, and to date more than 3000 species have been described distributed in 31 genera (Furman, 1953; Brennan and Goff 1977; Jacinavicius et al., 2018).

As other Parasitengona mites, chiggers from the Trombiculidae family have low host specificity and infest the different possible hosts in a given environment (i.e., nests, urbanized areas, forested areas, etc.) (O'Callaghan et al., 1994). Specifically, in ectothermic hosts, these mites attach on soft tissues of the skin and depending of the association of the mite-hosts, some animals have developed

Fig. 6 Scanning electron microscopy of leg segmentation of A) Trombiculidae (7-7-7) and B) Leeuwenhoeikiidae (6-6-6). Mendoza-Roldan, JA.

Fig. 7 *Eutrombicula alfreddugesi* larvae on *Kentropyx calcarata* lizard axillar mite-pocket. Modified from Mendoza-Roldan J, Rocha Ribeiro S, Castilho-Onofrio V, Gobbi Grazziotin F, Rocha B, Ferreto-Fiorillo B, Soares Pereira J, Benelli G, Otranto D, Barros-Battesti DM (2020) Host association of mites and ticks to reptiles and amphibians in Brazil. *Acta Tropica*, 105515.

microhabitats, also called “mite pockets”, that can be from cavities to folds of the skins, located generally in the armpit, groin and neck regions (Fig. 7). Chigger mites are generally ectoparasites, though some exceptions exist, such as species of the genera *Vatacarus* and *Iguanacarus* which are endoparasitic mites of the respiratory tract of marine snakes (*Laticauda* sp.) and iguanas (*Amblyrhynchus* sp.) (Nadchatram, 2006). The distribution and diversity of chigger mites is given by the environmental conditions, region and host availability. In this sense, species of medical and veterinary importance belong to the genus *Eutrombicula* Ewing, 1938 in the Neotropics and Nearctic, *Neotrombicula* Hirst, 1925 in the Palearctic and *Leptotrombidium* Nagayo et al., 1916 in the Oriental region.

***Eutrombicula alfreddugesi* (Oudemans, 1910)**

The most common species of trombiculid mite in the Americas is *Eutrombicula alfreddugesi*, having been recorded in almost all countries from Canada to Southern Argentina and the Caribbean basin. Given the plasticity and adaptability of this species, it has been reported infesting amphibians, reptiles, birds, and mammals, including humans (García-De la Peña, 2011; Mendoza-Roldan et al., 2020b). Depending on the ecoregion (i.e., temperate, tropical), larvae can be present year round or from summer to fall in the northernmost or southernmost part of its distribution. This species has been recorded as the causative agent of trombiculosis (dermatitis produced by the bite of the mite) (Clopton and Gold, 1993). Larvae of *E. alfreddugesi* are well adapted to temperatures ranging from 18 to 38 °C, and prefer high humidity (>80%) (Jameson, 1972). Parasitic larvae have an extra-oral digestion, feeding

on the detritus produced in the epidermis on which the mite attaches. Thus, larvae have preferences for microhabitats on the host that are of difficult access such as lower abdomen, ears, armpits (mite-pocket in lizards), genitalia, base of the tail, and around the anal/cloacal region (Rocha et al., 2008).

Females of *E. alfreddugesi* lay their eggs 15 days after fertilization. Eggs develop at different times in the female body, though they hatch all at the same time. Prelarvae hatch and develop to larvae in 15 days for each stage. Parasitic larvae emerge and can infest vertebrate host for two to 48 days depending if the host is endothermic (mammals or birds) or ectothermic (amphibians and reptiles). Engorgement periods on reptiles tend to be longer and the deleterious effects on the host are minor. After larvae detach from the host, they return to the environment where they develop to protonymph (inactive stage), deutonymph (active) which can last up to 40 days. Deutonymphs molt to quiescent tritonymph and 5 to 10 days later, adults emerge and can live up to 1 year and a half (Williams, 1946; Jenkins, 1948).

Neotrombicula autumnalis (Shaw, 1790)

Neotrombicula autumnalis (i.e., harvest mites) are of veterinary and medical concern in Europe. The six-legged larvae are hairy and measure from 250 to 750 µm according to the stage of repletion (Prosl et al., 1985; Parcell et al., 2013). Mites are reddish and have a pentagonal dorsal scutum. After females *N. autumnalis* lay eggs in humid organic-enriched soil, larvae hatch from eggs in late summer or early autumn (at temperatures around 16 °C) being prevalent on grass and fallen leaves in habitats characterized by overgrown gardens and parks or forest edges and dry meadows. In the environment, larvae quest for hosts and, in warm sunny days, they are particularly active in the afternoon. Clustering together in some spots, usually hundreds or even thousands of larvae attack massively individual animals at the thin-skinned areas of the body (Poliana, 2012; Schöler et al., 2006). The infestation appears like “orange powder” (Fig. 8). In dogs and cats, the preferred sites are the paws, the face (around the eye ring, bridge of the nose, ear pinnacle), (Fig. 9) and in the inguinal region. In sheep, larvae localize on the face and ears and in cattle on the basis of the tail and the inner thigh (Fig. 10) (Caputo et al., 2018). On the skin of the host, larvae feed of fluids caused by their piercings and fall to the ground after about 3 days where they molt to octopod nymphs and then adults. Usually, the development is interrupted by the hibernation in the environment (in deep soil) with one generation of mites developing per year. Lizards and snakes are suitable hosts also with high parasitic loads throughout the body, in between the scales. For example, a prevalence of *N. autumnalis* up to 70% was recorder in southern Italy, in *Podarcis muralis*, *Podarcis siculus* and *Lacerta bilineata* lizards (Fig. 11) (Mendoza-Roldan et al., 2019). Another species of *Neotrombicula* that has been recorded as possible causative agent of trombiculosis is *Neotrombicula inopinata* (Oudemans, 1909). This species has been identified mainly in Spain and Portugal, infesting dogs, cats and humans (Stekolnikov et al., 2014; Ramilo et al., 2019; Areso Apesteguía et al., 2019).

Leptotrombidium spp. Nagayo et al., 1916

The genus *Leptotrombidium* is distributed in eastern and southeastern Asia, New Guinea and northern Australia and cause a pruritic dermatitis in humans. About 15 species in that genus (e.g., *Leptotrombidium akamushi*, *L. deliense*, *L. pallidum*, and *L. scutellare*) act as vectors of a rickettsial disease, also known as scrub typhus, caused by *O. tsutsugamushi* in humans (Stekolnikov, 2013; Tilak and Kunte, 2019). The disease is known in Asia since the 16th- century being reported in Chinese manuscripts of natural history, and it is characterized by acute febrile presentation, severe headache, rash and lymphadenopathy lasting for 2–3 weeks (Xu et al., 2017). While the severity seems to vary according to the strain of the pathogen, a mortality exceeding 30% has been recorded in untreated cases. The multiple serotypes of *O. tsutsugamushi* characterized, may cause transient (non-protective) cross-immunity in humans (Bonell et al., 2017). Therefore, prompt treatment with tetracycline antibiotics (e.g., doxycycline and chloramphenicol) may prevent

Fig. 8 Larvae of *Neotrombicula autumnalis* around the labial commissure of a sheep, with the typical “orange powder” aspect. Lia, RP.

Fig. 10 Larvae of *Neotrombicula autumnalis* around the eyelid of a cow. Lia, RP.

Fig. 11 Larvae of *Neotrombicula autumnalis* on *Podarcis siculus* lizard in association with immature stages of *Ixodes ricinus*. Modified from Mendoza-Roldan JA, Colella V, Lia RP, Nguyen VL, Barros-Battesti DM, Iatta R, Dantas-Torres F, Otranto D (2019) *Borrelia burgdorferi* (sensu lato) in ectoparasites and reptiles in southern Italy. *Parasites & vectors*, 12(1), 35.

mortality cases. The strict association between scrub typhus and mites is proven by the fact that *tsutsugamushi* is a Japanese word meaning dangerous mite (Wee et al., 2017).

Although species of *Ascoschoengastia* and other genera of chiggers such as *Blankaartia*, *Gahrlepiea*, *Eutrombicula*, *Microtrombicula* and *Odontocarus*, have been found to carry and have been implicated in the circulation of *O. tsutsugamushi* among rodents, *Leptotrombidium* spp. play the primary role in the transmission of the scrub typhus. It results in the fact that, this zoonosis is associated with enzootic foci in rodents of the subgenus *Rattus* (*Rattus*), in transitional vegetation and in suitable habitats (also known as mite islands), whereas bird- and reptile-associated species (e.g., genus *Eutrombicula* and *Schoengastia*) do not carry *O. tsutsugamushi* (Elliott et al., 2019). This may ultimately explain the reason why the distribution of scrub typhus does not necessarily overlap that of scrub itch. Scrub typhus is also associated with man-made environments that may be suitable for the perpetuation of rodents (Elliott et al., 2019).

Considering the parasitic behavior of trombiculid larvae, which feed on one individual host, *O. tsutsugamushi* is transmitted transovarially from the adult female mites to the offspring. Accordingly, *O. tsutsugamushi* has been detected in almost all organs (e.g., salivary glands, reproductive organs) and tissues (e.g., epidermal cells) of larval and adult mites (e.g., *L. pallidum*), which therefore represent not only a vector of the pathogen but also the reservoir.

Therefore, the occurrence of scrub typhus is seasonal (e.g., in the coastal areas of south-east China during summer-autumn) and outbreaks have been associated with *L. pallidum* in gardens in the vicinities of the patients' households (Nagano Prefecture, Japan) (Kelly et al., 2009). Similarly, an outbreak in a suburb of Bangkok was related to a high exposure to *O. tsutsugamushi* in *R. rattus* population (96%), to the positivity in mites (*L. delicense* and *Ascoschoengastia* spp.) collected on them and (2%) and to positivity of 30% of the human population (Low et al., 2019).

Medical importance and control

The pathogenic effect of trombiculid mites on their host depends on the parasitic load and on the stylostome length, which varies according to the species of chigger (Tudor et al., 2015). Furthermore, the stylostome morphologic features, the host reaction to the chigger mite infestation (dermic response), could affect the capacity of mites in vectoring pathogens, among others (Fleming and Chastain, 1991; Shatrov and Felska, 2017). In general, the local reaction to the larva "bite" is imperceptible, whereas when chigger mites feed on humans or accidental hosts, they tend to produce dermatitis. This reaction is called chigger dermatitis or trombiculiasis (Guarneri et al., 2017a,b). Generally, the causative agent producing skin lesions goes undetected as larvae are typically small (100–300 µm) being barely visible to the untrained eye. Depending on the host and species of mite, they can be either red, orange or light yellow and even white. Usually, large number of larvae infest the host at once, resulting in multiple lesions and discomfort. In humans, mites tend to attach in regions near to the ankles, legs, lower body and arms (Guarneri et al., 2005). Lesions are produced by the liquefaction of the tissues surrounding the site of the attachment. This generates erythema, blisters, local alopecia, and crusty dermatitis. Depending on the number of mites and host reaction, persistent pruritus, excoriation and, in severe cases, convulsions may occur and last for some days until larvae fall into the environment. The diagnosis is confirmed by the anamnesis (e.g., season or contact with trombiculiasis foci), by the clinical presentation and the microscopic observation of mites (Santibáñez et al., 2015). Though, dermatitis disappears as soon as larvae abandon the hosts, treatment similar to that used for cheyletiellosis may be considered in pet dogs and cats with fipronil and selamectin or, in dogs, even with pyrethroids (Lecru et al., 2019). In humans exposed to trombiculid larvae in the environment the primary lesion are macupapulae, hemorrhagic and itchy. In rare cases, they may localize around the eyes and cause conjunctivitis. Humans frequenting habitats endemic for the scrub typhus should prevent the mite bites through the treatment of cloths or exposed skin with topical repellents (e.g., diethyltoluamide) or pyrethroids (e.g., permethrin), particularly in the parts of the body more likely to be exposed to larval mites (e.g., lower legs, ankles and feet) (Wee et al., 2017). Control of the rodent population is effective as a long-term measure to reduce scrub typhus. However, the risk associated with trombiculid larvae seeking alternative hosts (e.g., humans) should be considered if rodents are suddenly removed from the environment (Kim et al., 2018).

Other species of *Eutrombicula* can also produce trombiculosis in humans [i.e., *Eutrombicula splendens* (Ewing)]. Larvae of *E. splendens* can infest amphibians, reptiles, birds, and mammals, including humans, though its host preference remains within reptiles (e.g., snakes and turtles). *Eutrombicula splendens* occurs in sympatry with *E. alfreddugesi*, having also similar seasonality (Jenkins, 1949).

Leeuwenhoekidae Womersley, 1944

Mites from the family Leeuwenhoekidae are encompassed in 33 genera with approximately 230 species. Of these genera, two are of noticeable veterinary importance, i.e., *Hannemania* and *Straelensia*. The genus *Hannemania* (Fig. 12) are intradermic larvae typically associated with amphibians and includes 27 valid species, of which 26 occur in America and one in Oceania. Still, the status of 11 of these species is uncertain due to succinct descriptions and most of the type material is lost (Silva-De La Fuente et al., 2016). Larvae penetrate the skin and develop inside a capsule where the mite feeds of the debris and lysates of skin tissue, remaining for weeks and even months inside the capsule (Fig. 5). This capsular process produces an inflammatory response, that can result in cysts, pustules, and limb loss due to avascular necrosis (Wohltmann et al., 2006; Alvarado-Rybak et al., 2018). On the other hand, some species of

Fig. 12 Scanning electron microscopy *Hannemania hepatica* (Leeuwenhoekidae) larvae. Mendoza-Roldan, JA.

Straelensia larvae (e.g., *Straelensia cynotis* Fain & Le Net, 2000) can parasitize dogs and Iberian ibex in Europe, attaching within the inner surface of hair follicles, and forming intradermic solid nodules (Net et al., 2002; Fain and Le Net, 2000; Cevidanes et al., 2019).

Medical importance and control

Infestations by larvae of *Straelensia* are less pruritic than those caused by trombiculid mites, nonetheless, the distinctive nodular dermatitis produces macules that can be painful. Perifollicular edema and mucinosis can be observed at the cytologic examination, also with thickening of the epithelium. Skin nodules are generally small and firm, distributed mostly on the dorsal area of the head and body. Lesions evolve from erythematous papules to firm pale nodules. In most cases, the dermal response resolves within 3 months up to a year and treatment can be achieved with systemic avermectins, whereas topical acaricides are not useful (Net et al., 2002). To avoid mite attachment, it is important to ensure animals are not housed in infested places.

Etymology

A. Sarcoptidae: *Sarcoptes scabiei*. Greek: *sarx* = meat; *koptein* = twisted; Latin: *scaber* = rough, not clean; English: itch; scientific name of disease: scabies.

B. Demodicidae: *Demodex* species. Greek: *edemas* = body; *dex* = stretched.

Geographic distribution and epidemiology

Sarcoptes and *Demodex* species are both worldwide found in the skin of humans and many animals (as subspecies).

Biology and morphology

A. *Sarcoptes scabiei*: These so-called scabies mites (Figs. 1–3; Table 1) enter the epidermis of their hosts as soon as a female has been fertilized by a free ranging male on the skin of a host. Inside the epidermis, the females dig channels with a length of up to 1 cm (Fig. 4). Therein the females lay 1–4 eggs per day for up to 4 months. When hatched inside the epidermis channel the six-legged larvae feed on epidermis cells and become finally adults after passing two 8-legged nymph stages (Fig. 3). The development of the males and females inside the epidermis is different. It takes 12–15 days for females, but only 9–10 days in the case of males, which therefore reach the host's skin surface earlier than the females. These mites prefer special regions of the human skin (Fig. 5), within which the temperatures might be somewhat higher than in others. The adult females reach a size of $0.3\text{--}0.5 \times 0.2\text{--}0.4$ mm, while the males remain somewhat smaller (Fig. 1). The adults of this species can move 2–5 cm per minute. Thus, they can infest many regions of the host's skin before they enter the skin and dig a channel inside the stratum granulosum (Fig. 6). The females live therein for up to 60 days (Arlian et al., 1989, 2016; Castro et al., 2018; Mehlhorn, 2016a,b,c; Rider et al., 2015; Shen et al., 2018; Sary, 2010; Wei et al., 2019).

B. Demodicidae (Follicle mites): The follicle mites (*Demodex folliculorum*) and the mites of the sebaceous glands (*Demodex brevis*) measure as adults 0.3–0.4 mm in length and 0.2 mm in width. The body of both appears like a cigar (Figs. 7 and 8; Table 2). Their legs are clearly shorter than those of *Sarcoptes* specimens (Fig. 1). After copulation, the females lay several 70–90 $\times$ 20–25 μm sized eggs. From each egg hatches a six-legged larva, which molts into another larval stage or becomes directly a nymph, which molts also in time to become either the adult male or female. This development takes all in all up to 3 weeks, which is respectively rather quick and thus induces first skin lesion very soon after having reached a new host. The males stay on the host's surface. After several copulations with females they live mostly for only further 3–5 days, while the fertilized females enter the follicle region of the hair, where they depone about 20 fertilized eggs before they also die. The transmission of adult mites from host to host occurs by body-to-body contacts between humans or animal hosts, respectively.

Symptoms of disease

A. Scabies mites: Infections mainly start by occurrence of inflammation reactions in the region between the fingers, on sexual organs or along the groins, from where they may spread all over the body and thus even reach the head skin (Figs. 5 and 6). In the case of

Fig. 1 Diagrammatic representation of a female (left side) and a male stage of *Sarcoptes scabiei*. In the female, an egg is shining through.

Fig. 2 Light micrograph of an adult male of *S. scabiei* showing the ventral side. Note the long hair, which help to recognize the surroundings in a skin channel. The anterior legs are equipped with sucker-like structures on a stick.

Fig. 3 Scanning electron micrograph of a female scabies mite (*Sarcoptes scabiei*), which shows clearly the eight, very short legs, which enable the mites to move inside prepared channels of the epidermis.

Table 1 *Sarcoptes* species of humans and animals.

Species	Length (mm)	Hosts/habitat	Name of disease
<i>Sarcoptes scabiei</i>	♀ 0.3–0.5 ♂ 0.2–0.3	Humans/epidermis	Scabies
<i>S. canis</i>	♀ 0.3–0.4 ♂ 0.2–0.25	Dogs/epidermis	Mange
<i>S. suis</i>	♀ 0.4–0.5 ♂ 0.25	Pigs/epidermis	Mange
<i>S. bovis</i>	♀ 0.3–0.5 ♂ 0.2–0.3	Cattle/epidermis	Mange
<i>S. cuniculi</i>	♀ 0.3–0.4 ♂ 0.2–0.24	Rabbits/epidermis	Mange
<i>S. equi</i>	♀ 0.4–0.45 ♂ 0.25	Horses/epidermis	Mange

Note that also animal species might enter humans.

Fig. 4 Diagrammatic representation of the ongoing of the life cycle stages of *Sarcoptes scabiei* inside the epidermis of humans. As soon as adults have reached the surface of a host, they may become transmitted to other hosts during body contacts.

Fig. 5 Diagrammatic representation of a human skin region, on which the copulation occurs. After fertilization, the females enter the skin by digging a channel. Inside this channel they lay eggs, from which the larvae hatch and dig a channel from there to the surface of the skin. Transmission to other hosts occurs, when fertilized females enter another host during body contacts.

Fig. 6 Examples of three human skin regions being affected by scabies mites. Note that also sexual organs might be heavily infested.

Fig. 7 Scanning electron micrograph of numerous adults of *Demodex folliculorum*. Note their cigar-like body shape and 8 short legs (in blue) inside the host's epidermis, which enable them to dig tiny tunnels inside the host's epidermis.

Fig. 8 Light micrograph of a section through the skin of a dog, wherein several *Demodex* mites are cut.

Table 2 Life cycle data of the *Demodex* species of humans and animals.

Species	Hosts	Body size (μm)	Egg size (μm)	Main sites of infection
<i>D. canis</i>	Dogs	0.15–0.25	70–90 $\times$ 25	Head, anterior legs, belly, breast sides
<i>D. felis</i>	Cats	0.15–0.25	70–90	Head
<i>D. suis</i>	Pigs	0.27	80 $\times$ 25	Snout, eyelids, belly, inner side of legs
<i>D. bovis</i>	Cattle	0.4	80 $\times$ 50	Head, shoulder, anterior breast
<i>D. caprae</i>	Goats	0.45	80 $\times$ 50	Head, shoulder, anterior breast
<i>D. ovis</i>	Sheep	0.45	80 $\times$ 50	Head, shoulder, anterior breast
<i>D. equi</i>	Horses	0.4	60–80 $\times$ 40	Eyelids
<i>D. folliculorum</i>	Humans	0.4	70 $\times$ 40	Many places
<i>D. brevis</i>	Humans	0.25	70 $\times$ 40	Many places

immuno-suppressed persons, the spreading of the mites on the hosts is often especially intensive leading to large regions of destroyed, suppurating remnants of the epidermis (Fig. 6). The final appearance of such large regions with typical crusts or scabs is described as Norwegian scabies, which is especially often found at persons suffering from strong immunosuppression (i.e. in cases of AIDS). Infected persons have reported, that especially in the evening and night hours, scabies is accompanied by very intense itching.

The following aspects can be differentiated along human skin after an infection by scabies mites.

- Mite channels (Fig. 4): The mostly only 1–4 mm long channels inside the skin end in a terminal slightly enlarged bladder that surrounds the fertilized female excreting the eggs. These channels appear reddish to brownish and may contain blood after intensive scratching (Fig. 6).
- Secondary exanthema: This sign appears mostly as hypersensitivity reaction on antigenic material excreted by the skin-boring females. Eczemas are also often seen during this phase of infection.
- Hyperkeratotic skin crusts (Fig. 6): This symptom is especially often found in immunosuppressed adult humans as well as in children along the whole body and occurs also in the face. If the brownish crusts reach $\frac{1}{2}$ cm in diameter, the symptom is described as Norwegian scabies (Scabies norvegica).
- Superinfection by bacteria: in heavy infections, it occurs rather often that the “channels” in the skin become superinfected by bacteria thus inducing severe infections depending on the species.

B. Demodicidae: Although the infection rates of humans may increase up to 100% during lifespan and although occasionally up to 1000 mites may be present at the same time, clinical symptoms are rarely seen in healthy persons. However, especially immuno-suppressed people or animals may show keratinization besides rosacea, areata-like alopecia, pyoderma, lupus miliaris, blepharitis, perioral dermatitis and/or micropapular lesions (Bhat et al., 2017; Chen and Plewig, 2015; Gach and Heagerty, 2000; Zhong et al., 2019).

Diagnosis

A. *Sarcoptes scabiei*: Skin inspection: Infected skin shows pruritus, papulae – often combined with exanthemas - and tiny inflamed regions. Using needles female mites can be taken out from the skin channels, wherein they stay.

Skin scrapes: Using a fine scalpel, the infested skin region is scraped, whereby portions of the inflamed skin can be obtained. If this material is placed into a 10% potash alkaline solution for 5–30 min and afterwards studied by light microscope the developmental stages of the mites and/or their eggs might be diagnosed.

B: *Demodex folliculorum*: When squeezing the skin in affected regions, which often occur in the naso-labial zone, the obtained sebaceous material often contains the cigar-shaped mites (Fig. 7) or portions of them. They are rather small and thus only will be clearly seen by help of a light microscope, when the obtained material is mixed with a drop of concentrated lactase (Kido et al., 2017).

Pathway of infection

A. *Sarcoptes scabiei*: Transmission of adult fertilized females (= telonymphs) occurs, when a new host has got body contact with the skin of infected animals or humans.

B: *Demodex folliculorum*: Transmission of adults occurs during intense body-to-body contact with unknown persons or animals.

Prophylaxis

A. *Sarcoptes scabiei*: Infections can be blocked by avoiding skin-to-skin contact with infected persons or animals and by avoidance to wear long time unwashed clothes of other persons.

B: *Demodex folliculorum*: Regular hair and body wash using skin cleaning products.

Incubation period

A. *Sarcoptes scabiei*: It takes about 10–14 days until first human skin symptoms are seen.

B: *Demodex folliculorum*: It takes in general about 2–3 weeks until (if at all) symptoms (itching) occur. However, low-graded infections remain often hidden, nevertheless mites can be transmitted to other persons.

Prepatent period

A. *Sarcoptes scabiei*: The first stage of larvae can be found about 15 days after a fertilized female has entered the skin of a host. Low-graded infestations or especially invasions of single but fertilized females need weeks until first parasites are seen.

B: *Demodex folliculorum*: Same range like in *S. scabiei*.

Patency

A. *Sarcoptes scabiei*: Females live only for 2–3 months, however, many repeated self-infections due to produced progeny keep infections ongoing and lead often to spreading all over the body.

B: *Demodex folliculorum*: Years, since repeated self-infections may occur.

Therapy

Infections of both species can be treated with the chemical compound ivermectin, which originally had been developed to control worms. There are different product names in France (Stromectol®) and in Germany (Scabioral®). Since in a family the single members might have been infected at different times and thus may show not yet clear symptoms, it makes sense to treat them all at the same time to avoid repeated “ping-pong” infections (Alipour and Goldust, 2015; Demmler et al., 1997; Fromstein et al., 2018; Jacob et al., 2019; Khalil et al., 2017; Morgan et al., 2017; Nicholls et al., 2017).

Introduction

Ticks are the largest acarines and are obligate blood-feeding parasites of reptiles, amphibians, birds and mammals, in all or some of their developmental stages (Olivier, 1989; Keirans, 2009). They present an extensive distribution throughout all the six zoogeographical regions of the globe, being particularly abundant in the tropics (Keirans, 2009; Guglielmone et al., 2014). Nonetheless, ticks are also significant parasites of animals and humans in temperate forests, steppes, prairie habitats and even in the harsher tundra of the arctic (Keirans, 2009; Guglielmone et al., 2014).

The parasitic relationship between ticks and their hosts dates back to dinosaurs (Peñalver et al., 2017). In the course of their interminable evolutionary history, ticks evolved as primary parasites of wild animals, but some species have perfectly adapted to domestic animals as well. This is the case of brown dog ticks (*Rhipicephalus sanguineus* sensu lato), which have been infesting dogs since Ancient Egypt, at least (Huchet et al., 2013; Otranto et al., 2014b). Nonetheless, even ticks that are presently well adapted to domestic animals may still be able to parasitize wild animals. For instance, the cattle ticks *Rhipicephalus microplus* and *Rhipicephalus annulatus* are primary parasites of cattle, but can also infest wild bovids (Lohmeyer et al., 2018). Indeed, the increasing populations of wild bovids has compromised the success of the Cattle Fever Tick Eradication Program in South Texas (Lohmeyer et al., 2018). Ticks that frequently feed on both wild and domestic animals are often of medical and veterinary importance, not only for their ability to bite livestock, companion animals and humans, but also for their competence as vectors of a huge variety of pathogens to these hosts. Examples of such ticks are *Ixodes ricinus* in Europe, *Amblyomma americanum* in the United States and *Amblyomma sculptum* in South America, *Ixodes holocyclus* in Australia and *Ixodes persulcatus* in Asia.

Comparable only to mosquitoes, ticks are competent vectors of a long list of bacteria, protozoa, viruses, and helminths to animals and humans (Dantas-Torres et al., 2012a). Tick species of medical and veterinary importance are included in the families Ixodidae (hard ticks) and Argasidae (soft ticks), which will be in the spotlight in this chapter. The long evolutionary history of ixodid and argasid ticks has molded their biology and ecology, being their need to obtain a blood meal one of the main driving forces for their evolution (Mans et al., 2011). Ixodid and argasid ticks evolved in such a way that even within the same family ticks may present quite distinct biological life cycles, host specificity and habitat requirements. In the following sections, current aspects of tick origin, taxonomy and identification will be touched upon. General information on the medical and veterinary importance, biology, ecology, prevention and control of ticks are also discussed.

Origin and phylogenetic relationships

Pioneer hypotheses put the origin of ticks in the Paleozoic Era (in the Devonian, Carboniferous or Permian periods), as parasites of the ancestors of modern vertebrates such as reptiles and amphibians (e.g., Olivier, 1989; Dobson and Barker, 1999; Jeyaparakash and Hoy, 2009; Mans et al., 2011, 2016). Other authors believe that ticks originated in the Mesozoic Era, somewhere between the Triassic and Jurassic periods (e.g., Balashov, 1994; Beati and Klompen, 2019). However, fossil data indicate that ixodid and argasid ticks were already diverged in the Mesozoic Era, at least since the Cretaceous period (Poinar and Brown, 2003; Klompen and Grimaldi, 2001; Chitimia-Dobler et al., 2017; Estrada-Peña and de la Fuente, 2018). So far, no fossil evidence is available for the

Nuttalliellidae, but the fourth known tick family (Deinocrotonidae) was also described from Cretaceous amber (Peñalver et al., 2017), further indicating that nuttalliellid, deinocrotonid, ixodid and argasid ticks were already independent lineages during the Cretaceous period.

It has been postulated that ticks would have appeared in the African portion of the supercontinent Gondwana, during the Upper Carboniferous or Lower Permian, probably as parasites of diapsid or synapsid (Mans et al., 2016). This assumption is based on the restricted distribution of the species *Nuttalliella namaqua* (the only living representative of Nuttalliellidae, an ancestral lineage of ticks) as well as supported by molecular estimates (molecular clock) from the data of mitochondrial genes (Mans et al., 2016). However, an extinct species of tick, namely *Deinocroton draculi*, has recently been described based on specimens retrieved in a 99 million-year-old Cretaceous amber from Myanmar (Peñalver et al., 2017). From the morphological point of view, *Dc. draculi* [abbreviations of tick genera are according to Dantas-Torres, 2008, except for *Deinocroton* which was described afterwards] is closely related to *Nu. namaqua* and it is believed that they represent distinct evolutionary lineages that originated from a common ancestor (Peñalver et al., 2017). Unfortunately, no genetic data is presently available for *Dc. draculi*, which precludes any further consideration, which also is beyond the scope of this chapter. Nonetheless, the finding of *Dc. draculi* in Myanmar may suggest that ancestral lineages of ticks could have had a broader distribution in Gondwanan than previously thought, which calls into question the theory of the origin of ticks in South Africa (Dantas-Torres, 2018).

Phylogenetic analyzes indicate that all tick families and subfamilies are monophyletic (Mans et al., 2012). However, there are still doubts about the position of the Nuttalliellidae in relation to other extant tick families (i.e., Argasidae and Ixodidae) (Mans et al., 2016). In the past, it was believed that *Nu. namaqua* was the “missing link” in the phylogenic relationship of Argasidae and Ixodidae. Nowadays, it is accepted by some authors that the Nuttalliellidae occupies a basal position in relation to other extant tick families, representing the closest relative to tick ancestors (Mans et al., 2011). However, studies carried out with different molecular markers (mitochondrial and nuclear) have generated discrepant results in relation to the exact phylogenetic position of this family (Mans et al., 2012; Burger et al., 2014).

Taxonomy

Ticks are chelicerate arthropods (kingdom Animalia, phylum Arthropoda, subphylum Chelicerata), belonging to the class Arachnida, subclass Acari, superorder Parasitiformes and order Ixodida (=Metastigmata) (Keirans, 2009; Lindquist et al., 2009). This order is currently subdivided into four families: Argasidae, Ixodidae, Nuttalliellidae and Deinocrotonidae (extinct) (Dantas-Torres, 2018).

Out of over 50,000 named species of Acari, ~970 are tick species (updated from Dantas-Torres, 2018; Du et al., 2018; Kwak et al., 2018; Apanaskevich and Tomlinson, 2019; Apanaskevich et al., 2019; Barker, 2019; Dantas-Torres et al., 2019a; Martins et al., 2019; Sun et al., 2019; Labruna et al., 2020; Muñoz-Leal et al., 2020; Onofrio et al., 2020), eight of which have been described from fossil material. Ixodidae and Argasidae are the most speciose families with approximately 750 and 218 species, respectively. Species in the family Ixodidae are arranged in two major phyletic lines, namely Prostriata (all species in the genus *Ixodes*) and Metastriata (all other ixodid species) (Olivier, 1989). Prostriate ticks are the most ancient and primitive members of the Ixodidae (Black and Roehrdanz, 1988). Among metastriate ticks, those belonging to the genus *Haemaphysalis* are more ancient and primitive than other genera (Olivier, 1989).

The Ixodidae includes the following genera (approximate number of species in parentheses): *Africaniella* (2 spp.), *Amblyomma* (136 spp.), *Anomalohimalaya* (3 spp.), *Archaeocroton* (1 sp.), *Bothriocroton* (7 spp.), *Compluriscutula* (1 sp.), *Cornupalpatum* (1 sp.), *Cosmiomma* (1 sp.), *Dermacentor* (42 spp.), *Haemaphysalis* (173 spp.), *Hyalomma* (27 spp.), *Ixodes* (261 spp.), *Margaropus* (3 spp.), *Nosomma* (2 spp.), *Rhipicentor* (2 spp.), *Rhipicephalus* (86 spp.) and *Robertsicus* (1 sp.) (updated from Dantas-Torres, 2018). The species *Haemaphysalis cretacea*, which was described based on a nymph found in a Burmese amber from the Late Cretaceous (Chitimia-Dobler et al., 2018) is accounted for in the total number of ticks in the world, but not among the species of *Haemaphysalis*, due to uncertainties regarding the generic classification of this species.

The genus-level classification of the Argasidae has been the subject of ongoing discussion (Mans et al., 2019). However, the most frequently adopted classification includes the following genera (approximate number of species in parentheses): *Antricola* (17 spp.), *Argas* (62 spp.), *Nothoaspis* (3 spp.), *Ornithodoros* (134 spp.) and *Otobius* (2 spp.).

Identification

Ticks are large mites, whose size varies according to developmental stage and species; the largest ticks may reach over 30 mm in length (Keirans, 2009). Ixodid and argasid ticks are quite polymorphic (Figs. 1 and 2). The main morphological differences between ixodid and argasid ticks are summarized in Table 1. Although adults of some species have vestigial hypostome (e.g., *Otobius* spp., *Antricola* spp., some species of the genus *Ornithodoros* and some nidicolous males of the genus *Ixodes*), the vast majority of ticks have well-developed hypostome, covered with retrograde denticles, which are designed to anchor the tick into the host skin during the feeding phase. Ticks have no antennae, epistome, corniculi or tritosternum (Keirans, 2009). The palps are divided into four segments (articles I–IV) and can vary in morphology. In the tarsus I of all post-embryonic stages, a sensory organ called Haller's organ is present. This organ is designed to receive chemical, olfactory and microclimatic stimuli.

Fig. 1 Dorsal (A) and ventral view (B) of the bat tick *Ornithodoros kelleyi*. Ventral close-up views of a male (c) and a female (d) of the same species are also depicted. Main anatomical structures of taxonomic interest are indicated. Photos courtesy of CDC/William L. Nicholson and Jim Gathany, Public Health Image Library.

A single pair of eyes (ocelli) may be present or absent. When present, they are located on the lateral margins of the dorsal shield in ixodid ticks and in the supracoxal folds in argasid ticks. The larvae are hexapods and do not have spiracular plates. Nymphs and adults have four pairs of legs and have spiracular plates. Larvae and nymphs are sexually immature, having no genital opening. Larvae of most known species of argasid ticks have a dorsal plate, absent in nymphs and adults of this family; nymphs and adults of *Nothoaspis* spp. have a leathery dorsal shield, generally called pseudoscutum.

Ixodids have only one nymphal instar (=stadium). Argasid ticks have several nymphal instars; generally, three to four in most species, but may be five to eight in other species (Olivier, 1989; Apanaskevich and Olivier, 2013). Nymphal instars vary in size, but are essentially identical from the morphological point of view. In general, argasid ticks show little sexual dimorphism, whereas males and females of ixodid ticks can be easily differentiated by the dorsal scutum, which is anterior (podonotal) in females and complete (holonotal) in males. The male dorsal scutum is also called conscutum (Figs. 1 and 2).

The morphological determination of some species of ticks can be difficult. Taxonomic keys for the identification of tick genera and species can be found in reference books (e.g., Walker et al., 2000; Keirans, 2009; Durden and Beati, 2013; Estrada-Peña et al., 2017b; Nava et al., 2017) or papers (e.g., Martins et al., 2014a; Dantas-Torres et al., 2019a). A recent useful review listed 216 references which cover all tick species reported as permanent residents of the Western Palearctic, including 28 species of the genus *Ixodes*, two *Dermacentor*, seven *Haemaphysalis*, nine *Hyalomma*, eight *Rhipicephalus*, five *Argas* and about seven species of *Ornithodoros* (Estrada-Peña et al., 2017a).

Some morphological characters can be difficult to observe in fed specimens (especially engorged larvae, nymphs and females), poorly preserved (e.g., with modified ornamentation pattern of the scutum), or even damaged (e.g., without hypostome). Likewise, some species can be very similar in one or more stages of development. For example, males from *Amblyomma cajennense* and *Am. sculptum* cannot be morphologically distinguished with certainty and, therefore, molecular identification is the only way to unequivocally separate them (Nava et al., 2014; Martins et al., 2016). In fact, the molecular identification of ticks has contributed

Fig. 2 Dorsal view of a male (A) and a female (B) of South American yellow dog tick, *Amblyomma aureolatum*. Main anatomical structures of taxonomic interest are indicated. Photos courtesy of CDC/Dr. Christopher Paddock and James Gathany, Public Health Image Library.

significantly to the differentiation of species that are difficult to recognize morphologically, to the discovery of new species, as well as to the revalidation of species previously placed in synonymy.

Concerning the molecular identification of ticks, ribosomal nuclear DNA genes (18S and 28 rRNA) are generally more informative at the family and subfamily levels. Mitochondrial genes (e.g., cytochrome *c* oxidase subunit 1, 12S rRNA and 16S rRNA) and transcribed internal spacers (ITS1 and ITS2) provide better resolution at the level of genus and species. Mitochondrial sequences from closely related ticks should be interpreted with caution, considering that paternal leakage and mitochondrial DNA heteroplasmy may occur (Mastrantonio et al., 2019). It is also worth mentioning data bases such as Genbank (<https://www.ncbi.nlm.nih.gov/genbank>) may contain doubtful or even incorrect information, as there is no strict control over the accuracy of the information submitted (e.g., morphological identification). It is not uncommon to find sequences erroneously attributed to a particular species. Therefore, users of these databases should always pay attention to the use of reference sequences for the species under study. These sequences can be found in taxonomic papers (e.g., Dantas-Torres et al., 2012c; Nava et al., 2014, 2018), but also in reference books (e.g., Nava et al., 2017).

Next-generation sequencing (NGS) has been suggested as a useful tool in the search for new nuclear and mitochondrial markers for the study of tick systematics (Mans et al., 2015). The matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) has been used to identify ticks and detect pathogens in these arthropods (Diarra et al., 2017). In practice, NGS and MALDI-TOF MS are restricted to a few laboratories.

Table 1 Principal morphological differences between argasid and ixodid ticks.

Structure	Argasidae	Ixodidae
Coxal glands	Present in nymphs and adults	Absent
Eyes	When present, they are located in the supracoxal folds	When present, they are located at the margins of the scutum
Festoons	Absent	Present (except in <i>Ixodes</i> spp., <i>Margaropus</i> spp. and <i>Rhipicephalus</i> (<i>Boophilus</i>) spp.)
Gnathosoma	Ventral (except in larvae, in which it is terminal)	Terminal
Integument	Wrinkled, granulated, leathery, mamillated or tuberculated (except in adults of <i>Ornithodoros marinkellei</i> , in which it is smooth with small punctations)	Smooth (scutum and ventral plates) or striate (soft parts of the integument), with punctations that vary in size, deepness, number and localization
Palps	Four subequal articles (except <i>Or. marinkellei</i> and <i>Nothoaspis</i> spp., in which the article I is broader and differs from other articles)	Four articles of various size and forms, being the article IV reduced and recessed within a cavity of article III
Porose areas	Absent	Present
Scutum	Absent in nymphs and adults (except in <i>Nothoaspis</i> spp. that have a pseudoscutum); larvae may present a dorsal shield	Present in larvae, nymphs and adults
Spiracular plates	Situated between coxae III and IV	Situated after coxae IV

Medical and veterinary importance

Ticks can cause direct damage to the host, whose degree of severity will depend on characteristics of the infesting tick species as well as on the intensity of infestation (i.e., number of ticks per infested host). When ticks insert their mouthparts (i.e., hypostome and chelicerae) into the host skin (Richter et al., 2013), they can produce a local wound, which may facilitate secondary bacterial infections or infestation of larvae causing myiasis. Due to their extreme blood-feeding capabilities (discussed in detail below, in the section *Biology and ecology*), ticks can cause blood depletion, potentially leading to anemia in massively infested animals, particularly in young animals, malnourished and in the presence of polyparasitism. In addition, tick infestations can be a nuisance, causing irritation and decline of infested animals. Components of tick saliva can also cause allergy and paralysis (also known as tick toxicosis). Last but not least, ticks are mostly important due to their ability to transmit a multitude of pathogens to animals and humans (Jongejan and Uilenberg, 2004; Dantas-Torres et al., 2012a). It is worth mentioning, however, that many microorganisms detected in ticks are non-pathogenic or are presently of unknown pathogenicity (Ogrzewalska et al., 2019).

In the tropics, ticks are important parasites of livestock. The direct damage caused to the host and the morbidity and mortality attributable to tick-borne diseases (e.g., anaplasmosis, babesiosis and theileriosis) are responsible for a considerable economic burden to the livestock industry (Jongejan and Uilenberg, 2004; Dantas-Torres et al., 2012a; Estrada-Peña et al., 2020). Companion animals, especially dogs, are also frequently exposed to ticks and tick-borne pathogens, including bacteria (e.g., *Ehrlichia* spp. and *Rickettsia* spp.) and protozoa (e.g., *Babesia* spp. and *Hepatozoon* spp.). In the same way, many ticks primarily associated to wild animals, livestock and/or companion animals may infest and eventually transmit pathogens to humans. In fact, diseases such as Lyme borreliosis (caused by *Borrelia burgdorferi* and some related genospecies), ehrlichiosis (*Ehrlichia chaffeensis*, *Ehrlichia ewingii* and *Ehrlichia muris euclairensis*), human granulocytic anaplasmosis (*Anaplasma phagocytophilum*), rickettsioses (*Rickettsia rickettsii*, *Rickettsia conorii*, *Rickettsia massiliae*, *Rickettsia parkeri*, *Rickettsia africae* and many others), and tick-borne encephalitis (tick-borne encephalitis virus, a member of the family *Flaviviridae*) are responsible for considerable morbidity and mortality in humans around the world (Dantas-Torres et al., 2012a; Parola et al., 2013; Portillo et al., 2015; Madison-Antenucci et al., 2020).

Tick-borne diseases are on the rise worldwide (Dantas-Torres et al., 2012a; Dantas-Torres, 2015; Madison-Antenucci et al., 2020). Among the main factors linked to increase risk of this group of diseases, climate change, increased outdoor activities, global traveling, urbanization, natural environment encroachment, deforestation, habitat fragmentation should be mentioned. Through different mechanisms, these factors may promote or increase the contact between ticks, wildlife, livestock, companion animals and humans, thus creating a suitable environment for tick-borne pathogen transmission to occur (Dantas-Torres, 2015).

Ticks typically become infected while feeding on an infected host, which may be infected by one or multiple pathogens (Otranto, 2018). Indeed, ticks, animals and people may be co-infected by multiple pathogens (de Caprariis et al., 2011; Latrofa et al., 2014; Otranto et al., 2014a; Wormser et al., 2019). Ticks may also become infected through co-feeding with infected ticks on the same host and this play an important role in the transmission dynamics of certain pathogens (e.g., *B. burgdorferi*) (Belli et al., 2017; States et al., 2017). In some instances, ticks may pass the infection from one developmental stage to another (i.e., transstadial transmission) or from their mother to the offspring (transovarial transmission). Besides the feeding habits in terms of feeding periodicity and host range, transstadial and transovarial transmission play a key role in determining the infection rates in ticks in nature. For instance, transovarial transmission of *R. rickettsii* is inefficient in *Am. sculptum* (the principal vector of this bacterium in South America) but highly efficient in *Amblyomma aureolatum* (a vector in the metropolitan region of São Paulo) (Labruna et al., 2011). The prevalence

of *R. rickettsii* in *Am. sculptum* in Brazil is very low (i.e., 0.05–1.28%), even in areas the Brazilian spotted fever is endemic (Costa et al., 2020). Populations of this tick species from areas where Brazilian spotted fever cases have not been reported seem to be devoid of *R. rickettsii* infection (Dantas-Torres et al., 2019c; Gerardi et al., 2019). This can be attributed to an insufficient number of competent amplifying hosts (e.g., capybaras), a low susceptibility of the tick population to *R. rickettsii*, or both. Indeed, a recent study assessing six geographically distinct populations of *Am. sculptum* showed that the frequency of *R. rickettsii* transovarial transmission in this tick may vary according to population (Gerardi et al., 2019).

A great deal of data regarding the infection of ticks with a variety of pathogens has been accumulated since the advent of molecular biology techniques. A meta-analysis of the prevalence of *B. burgdorferi* sensu lato in questing nymphs in Europe revealed that prevalence by different genospecies (e.g., *Borrelia afzelii*, *Borrelia garinii* and *Borrelia valaisiana*) range from <1% up to >90% (Estrada-Peña et al., 2018). Prevalence in ticks was associated with environmental factors, with highest prevalence occurring in areas of 6.85°–16.85°C of average annual temperature and a slow spring rise of temperature, together with a moderate spring rise of vegetation vigor (Estrada-Peña et al., 2018). Some tick-transmitted pathogens may exert a deleterious effect on their tick vectors, as it is the case of *Rickettsia conorii* and *Rh. sanguineus* s.l. (Levin et al., 2009; Parola et al., 2009). This fact may partly explain the generally low prevalence (usually <1%) of *R. conorii* and *Rh. sanguineus* s.l. in nature (Parola et al., 2009).

Tick-borne pathogen transmission primarily occurs during tick blood feeding. Exceptions are protozoa of the genus *Hepatozoon* spp., whose transmission occurs through the ingestion of ticks harboring mature oocysts or eventually by predation of infected prey (Johnson et al., 2009; Baneth, 2011). During the course of blood feeding, transmission times (i.e., time elapsed from the tick attachment to the actual transmission of the pathogen) may range from minutes to hours or days (Saraiva et al., 2014; Eisen, 2018; Otranto, 2018). Transmission times are governed by features of the pathogen itself, but may also be influenced by other factors, such as interrupted feeding. For instance, it has been demonstrated that unfed nymphs and adults of *Am. aureolatum* had to be attached to the host for >10 h to transmit *R. rickettsii* (Saraiva et al., 2014), the agent of the most severe form of spotted fever in the western hemisphere (Dantas-Torres, 2007). On the other hand, fed ticks required only 10 min to transmit the bacterium to naïve hosts (Saraiva et al., 2014). This difference was attributed to the so-called reactivation phenomenon. In practice, *R. rickettsii* remain in a nonvirulent state in unfed ticks, whereas pre-feed ticks carry the bacteria in their virulent state (i.e., reactivated). It means that the pre-feeding can revert the bacteria to a virulent state, promoting their multiplication and shortening their transmission time when blood feeding is resumed on a new or even on the same host.

All the above-mentioned aspects inherent to tick-borne pathogen transmission are pivotal for understanding the mechanisms through which hosts become infected and thereby to establish refined prevention and control strategies.

Biology and ecology

Because of their medical and veterinary importance, ticks have been a recurrent subject of biological and ecological studies. A great deal is known about various aspects of tick life cycles, including feeding, reproduction, host specificity, habitat requirements and seasonal patterns (Olivier, 1989; Vial, 2009; Apanaskevich and Olivier, 2013; Gray et al., 2013). The following sections provide an overview on general aspects of tick biology and ecology. For more details, readers are advised to consult reference books on ticks (e.g., Bowman and Nuttall, 2008; Sonenshine and Roe, 2013a,b).

Feeding

Ticks are obligatory blood feeders. Ixodid ticks feed once in all developmental stages (larva, nymph and adult), with the exception of males of some *Ixodes* spp. that have rudimentary mouthparts and do not feed (Gray et al., 2013). Argasid larvae and nymphs generally feed once, whereas adults feed several times. However, if less than a critical amount of blood has been imbibed, a nymph may feed twice before ecdysing to the next nymphal instar (Olivier, 1989). Moreover, adults of some species (e.g., *Otobius* spp. and *Antricola* spp.) that possess rudimentary mouthparts do not feed. Similarly, larvae (e.g., *Ornithodoros savignyi*) and first-instar nymphs (e.g., *Ornithodoros fonsecai*) of some argasid species are able to molt without feeding (Olivier, 1989; Santiago et al., 2019).

When ticks are on the host and find a suitable place to feed on, they use their two chelicerae to pierce the skin of the host (Richter et al., 2013). Then, a breaststroke-like motion, effected by synchronous flexure and retraction of both chelicerae, causes the barbed hypostome to enter the host's skin (Richter et al., 2013). The buccal canal of the tick is formed by the dorsal surface of the hypostome and the ventral surfaces of the chelicerae (Richter et al., 2013).

The blood feeding process of ticks may last from hours to several days, depending on species and developmental stages. While feeding, ticks inject their saliva into the bite wound, which contains several active molecules, including anti-coagulants and inhibitors of blood clotting, kinases, vasodilators, and inhibitors of host defense (Mans and Neitz, 2004). Many ticks also secrete a cement-like substance, which is produced by the salivary glands, forming a prominent feeding cone that helps tick attachment (Richter et al., 2013).

Ixodid larvae and nymphs feed for days before molting to the next developmental stage. Larvae of most species of argasid ticks also remain on the host for several days, although larvae of some species (e.g., *Argas cucumerinus*) may feed for some minutes only. In general, nymphs and adults of argasid ticks feed for short periods (usually from 30 min to a few hours) (Olivier, 1989). Ixodid females generally feed for several days before laying eggs.

Ticks have developed an extraordinary capacity of survival without a blood meal, particularly argasid ticks. Ixodid ticks can survive for more than 1 year without a blood meal, but not much longer than that (Dantas-Torres et al., 2012b). On the other hand, argasid ticks are more capable to fast and some species are well adapted to the harsh, dry, low-host-density environments. As an example, unfed larvae of *Ornithodoros lahorensis* can live for a year and unfed adults can survive for 18 years without a blood meal (Hoogstraal, 1985). This long-term survival capability allows argasid ticks to linger in inhospitable places (e.g., remote desert areas), where host availability may be limited.

Feeding rhythm is definite in most ticks. The feeding cycle is comprised of periods of sucking, salivation and resting. For instance, sucking activity of *Rh. microplus* reach a peak at night, decrease in the morning and during the day, increasing again in the evening (Olivier, 1989). In a similar manner, ixodid ticks and larvae of some argasid ticks exhibit a definite daily rhythm of detachment from the host (i.e., drop-off rhythm), which is usually coordinated with the host's activities (Olivier, 1989; Dantas-Torres, 2010). For instance, engorged larvae of *Rh. sanguineus* s.l. detach from dogs predominately during daylight hours, whereas engorged nymphs and females exhibit nocturnal drop-off rhythm (Hadani and Rechav, 1969; Jacobs et al., 2004; Paz et al., 2008). Indeed, most ticks will detach while the hosts are in their nests, burrows, or other sheltered places (Olivier, 1989). Another interesting case is the synchronism between *Haemaphysalis leporispalustris* and rabbits, with this tick species dropping from the rabbit primarily during daylight hours when the rabbits are in their nests and only rarely during nocturnal hours (George, 1971).

Hyperparasitism (i.e., the parasitism of a parasite by another parasite), seems to be not uncommon among conspecific argasid ticks (Votava et al., 1974; Moorehouse and Heath, 1975; Helmy et al., 1983; Oliver et al., 1986; Endris et al., 1991; Williamson and Schwan, 2018). It has been wondered that this may reflect an earlier predatory origin of parasitism (Olivier, 1989). This may also be a strategy of fasting ticks sharing the same niche with fed ticks that have had a meal. A recent experimental study reported that 78.6% of *Ornithodoros hermsi* males (114/145) fed on conspecific engorged ticks (Williamson and Schwan, 2018). Unfed females and nymphs also fed on other ticks but far less frequently (only 6.7% combined; 17/254). Remarkably, unfed males acquired *Borrelia hermsii* when parasitizing nymphs that had recently engorged on a bacteremic mouse, and unfed infected males transmitted spirochetes to recently engorged nymphs (Williamson and Schwan, 2018). Finally, some ticks infected via hyperparasitism subsequently transmitted *B. hermsii* to mice. The real meaning of this behavior in nature remains poorly known.

Exceptional cases of hyperparasitism have been reported in ixodid ticks (Labruna et al., 2007; Durden et al., 2018; Buczek et al., 2019) and are reputed to be more common in *Ixodes* males (Olivier, 1989). Considering the low frequency and paucity of reports on this phenomenon in ixodid ticks, one may argue that the biological meaning of hyperparasitism for ixodid ticks is probably null.

Mating

As in other arthropods, mate-finding and courtship behavior in ticks are mostly regulated by pheromones of several types, including on-host sexual aggregation pheromones secreted by female metastriate while feeding (Kiszewski et al., 2001). Copulation of ticks can occur on hosts and in the environment. Argasid ticks always copulate in the environment, except *Argas transversus*, a very unique tick that mates on the host (Hoogstraal et al., 1973). Ixodid ticks of the genus *Ixodes* (Prostriata) produce spermatids even before feeding and generally copulate in the environment, but eventually also on the host (Olivier, 1989). One exception to this rule is *Ixodes trianguliceps*, whose males copulate solely on their hosts (Randolph, 1980).

Male ticks belonging to other genera (Metastrata lineage), on the other hand, typically attain sexual maturity and mate solely on their hosts (Kiszewski et al., 2001). Rare exceptions are the species *Bothriocroton hydrosauri*, *Bothriocroton concolor* and *Amblyomma triguttatum* whose males may produce spermatids without feeding (Guglielmone and Moorhouse, 1983; Oliver and Stone, 1983). Moreover, unfed males of *Am. triguttatum* can even transfer spermatids to females off the host (Guglielmone and Moorhouse, 1983).

When a male tick attains venter-to-venter contact with a female, mating proceeds through a succession of events (spermatophore formation and transfer), which culminates in fertilization of the female. The spermatophore transfer generally occurs in less than a minute, but males and females may remain in sexual contact for several days (Kiszewski et al., 2001).

The degree of copulatory penetration varies among ixodid and argasid ticks (Kiszewski et al., 2001). While copulating, argasid males insert their chelicerae, hypostome and pils into the females' genital pore (Feldman-Muhsam and Borut, 1971). As far as ixodid ticks, metastriate males insert only the tip of their chelicerae, whereas prostriate males introduce both their chelicerae and hypostome (Kiszewski et al., 2001). Metastriate males are able to copulate several times and take blood meals between copulas (e.g., males of the lone star tick *Am. americanum* can inseminate up to 37 females; Gladney and Drummond, 1970).

Males of some tick species are extremely rare, as it is the case of the rotund tick *Amblyomma rotundatum* (Sanches et al., 2012; Luz et al., 2013). Indeed, this tick species is considered to be obligatory parthenogenetic and capable of producing diploid female offspring by thelytoky (Olivier, 1989; Sanches et al., 2012), that is, the production of diploid daughters from unfertilized eggs. While extremely rare, males of *Am. rotundatum* have been found in nature (Labruna et al., 2005; Martins et al., 2014b; Gianizella et al., 2018), which is intriguing and raises the question whether this species is also able to reproduce bisexually, as it happens with other ixodid species. Indeed, sporadic parthenogenesis in normally bisexual species of ixodid and argasid ticks may occur, but it is generally considered of little practical significance as the few larvae produced are generally weak and soon die (Olivier, 1989; Kiszewski et al., 2001). However, parthenogenetic races of normally bisexual species could possibly emerge from such occurrences, which appears to be the case in *Haemaphysalis longicornis* (Olivier, 1989).

Females of some species of argasid ticks are able to lay eggs without feeding on blood, a trait named autogeny. Autogeny may be facultative (e.g., *Argas persicus*, *Or. lahorensis*, *Ornithodoros tartakovskyi*, *Ornithodoros tholozani* and *Or. fonsecai*) or obligatory (e.g.,

Otobius spp., *Antricola* spp. and probably *Nothoaspis* spp.) (Olivier, 1989; Kiszewski et al., 2001; Santiago et al., 2019). Autogeny has not been reported for ixodid ticks.

In addition to fulfilling its basic role of egg fertilization in bisexual species, mating is very important in regulating ixodid feeding and reproductive behavior (Olivier, 1989; Kiszewski et al., 2001). In fact, most ixodid females will not complete engorgement until mated. After mating, they will enter the rapid engorgement phase and soon drop from the host. Fed females are positively geotropic and negatively phototactic. So, they usually find a secluded place for oviposition, which occurs soon thereafter, unless an ovipositional diapause occurs (Olivier, 1989).

Oviposition

The preoviposition and oviposition periods may vary according to biotic and abiotic factors, lasting from a few days to several weeks (Troughton and Levin, 2007; Dantas-Torres et al., 2011). Temperature is critical factor (Olivier, 1989).

Ixodid females present a single gonotrophic cycle. After laying her single egg batch, the female stays alive for some days and then die (Dantas-Torres et al., 2011; Apanaskevich and Olivier, 2013). Ixodid females lay in average a few thousand eggs (Troughton and Levin, 2007). However, the amount of eggs laid by each single female varies from species to species and also according to other factors such as the amount of blood ingested (Dantas-Torres et al., 2011). For example, *Haemaphysalis inermis* females usually deposit a few hundred eggs (Apanaskevich and Olivier, 2013), whereas large *Amblyomma* spp. and *Hyalomma* spp. females can produce impressive numbers of eggs. There is a record of laying 38,732 eggs by a female of *Amblyomma variegatum* (Dipeolu and Ogunji, 1980). Partially engorged, fertilized females can also oviposit, but typically lay a lower amount of eggs.

Unlike ixodid females, argasid females may have various gonotrophic cycles and lay several batches of eggs, which are intercalated by periods of feeding and blood digestion. Interestingly, argasid females use only a portion of the ingested blood for egg production, storing the remainder for subsequent gonotrophic cycles or for their sustenance during long starvation periods (Olivier, 1989). Interestingly, females of some argasid species (e.g., *Argas arboreus*, *Argas boueti*, *Argas brumpti*, *Ar. transgarepinus*, *Ornithodoros moubata* and *Ornithodoros salahi*) show a brooding behavior over their eggs during incubation, whereas others (e.g., *Antricola marginatus*, *Argas striatus* and *Argas transgarepinus*) present a maternal behavior (carrying of larvae on the idiosoma) (Olivier, 1989; Labruna et al., 2012; Pienaar et al., 2018). Brooding may last for a few days or until hatching (e.g., in *Ar. arboreus*), or even through the inactive larval stage until nymphs emerge (e.g., in *Or. moubata*) (Jobling, 1925; Hafez et al., 1972). It has been supposed that maternal behavior may be an evolutionary adaptation to ecological challenges in inhospitable habitats for larval survival (Pienaar et al., 2018). Nonetheless, both maternal and brooding behaviors are still poorly investigated.

Host specificity

Ixodid and argasid ticks feed on a wide variety of reptiles, amphibians, birds and mammals. Some ticks accept a broad range of host species (i.e., generalists), whereas others are more selective (i.e., specialists) and feed on a narrow group of host species (Hoogstraal and Aeschlimann, 1982; Olivier, 1989).

A comprehensive study based on 43,615 records for 223 species of African ticks concluded that 14 species were generalists and 39 were potential specialists (Cumming, 1998). Data available at that time were insufficient for any conclusion regarding host preference for the remainder species. On the other hand, a relatively more recent meta-analysis based on 4172 records from Neotropical hard ticks concluded that strict host specificity is uncommon (Nava and Guglielmone, 2013). An example of a medically important generalist tick in the Neotropical region is *Am. sculptum* (Martins et al., 2016). This tick species may feed on capybaras, anteaters, tapirs, foxes, maned wolves, coatis, horses, dogs, among others (Martins et al., 2016; Ramos et al., 2020). It is also a very aggressive tick that bites humans, particularly nymphs and adults (Szabó et al., 2020).

In anthropic environments, domestic animals may act as the principal hosts for certain tick populations (e.g., dogs for *Rh. sanguineus* s.l. and cattle for *Rh. microplus*). However, wild animals (e.g., rodents, marsupials, foxes, lizards, snakes, iguanas, tortoises, bats and birds) may also act as primary hosts for tick populations in anthropic environments. For instance, capybaras are the main hosts of *Am. sculptum* in anthropic areas in São Paulo, southeastern Brazil (Luz et al., 2019). In the same way, white-tailed deer (*Odocoileus virginianus*) are important hosts for *Ix. scapularis* in urban parks in New York, United States (VanAcker et al., 2019).

As for ixodid ticks, host specificity varies in argasid ticks. Some groups of argasid ticks feed exclusively or predominately on bats, birds, toads or lizards (Dantas-Torres et al., 2012c; Muñoz-Leal et al., 2016, 2018b; Sándor et al., 2019; Venzal et al., 2019). On the other hand, some argasid may be generalists and feed on bats, marsupials and humans as well (Labruna et al., 2014).

The tick-host relationship is also an important factor driving the distribution of ticks. Exotic pets, migratory birds and also livestock may contribute to the dispersion of ticks and their associated pathogens in different habitats and regions (Brianti et al., 2010; Falchi et al., 2012; Hasle, 2013; Medlock et al., 2018; Bilbija et al., 2019).

Habitat and distribution

With some exceptions, ixodid and argasid ticks spend the bulk of their lives in the environment, where they are under the selection pressure of several abiotic factors. Habitat requirements of ticks directly influence their nonparasitic stages and may also affect their chance of finding a new host (Olivier, 1989; Dantas-Torres, 2010). In fact, most argasid ticks and many *Ixodes* species have adopted a

nidicolous life cycle strategy and live in nests, caves, burrows, or in human and livestock habitations (Olivier, 1989; Vial, 2009), which may provide a more stable microclimate and also increased protection from predators. Nonetheless, cave-dwelling argasid ticks may be targeted by predators such as spiders (Bernardi et al., 2010). While relatively uncommon, ixodid ticks may also be found in caves. Some *Ixodes* ticks primarily inhabit bat caves (Hornok et al., 2014), whereas others may sporadically be found in caves (Dantas-Torres et al., 2009), probably being transported by animals living nearby or visiting those caves.

Ixodid ticks live in a variety of habitats, including in tropical and temperate forests, steppes, prairie habitats, and even in the harsher tundra of the arctic (Keirans, 2009; Guglielmone et al., 2014). Some argasid ticks are able to endure in remote inhospitable areas. They are able to subsist in arid and hot environments, thanks to the peculiar nature of oilskin and cement components of their cuticle, which makes it highly resistant and reduces water evaporation (Vial, 2009). For instance, *Or. moubata* and *Or. savignyi* tolerate air temperature up to 63 °C and 75 °C, respectively (Vial, 2009). Many ixodid ticks are also able to survive in dry and hot environments, such as deserts and xeric shrublands (Guglielmone et al., 2014).

Some ticks may be exclusively found in primary forests, whereas others may be adapted to rural and urban environments. A recent study conducted in the Atlantic forest ecoregion in Argentina concluded that forest environments are more suitable habitats than agricultural and urban environments for many native tick species (Lamattina et al., 2018). On the other hand, forest environments were considered unsuitable for exotic species that have successfully established in environments that have been modified by man (Lamattina et al., 2018). The same tick species may be found in a range of habitats, but may be more abundant in a particular type of habitat. As such, living in certain types of habitats (e.g., grasslands) may be a significant risk factor for tick infestation in some hosts (Zanzani et al., 2019).

The ability of ticks to occupy a wide range of habitats partly explains their wide geographical distribution. Indeed, some tick species may present a broad distribution in different countries or continents (e.g., *Rh. microplus*). Information on ixodid tick distribution in the world zoogeographical regions (i.e., Afrotropical, Australasian, Nearctic, Neotropical, Oriental and Palearctic regions) has been exhaustively compiled elsewhere (Guglielmone et al., 2014). Some tick genera (e.g., *Ixodes*, *Haemaphysalis*, and *Amblyomma*) are found in all six zoogeographical regions, whereas others are more restricted in distribution. For instance, *Anomalohimalaya* (three species) is exclusive to the Palearctic, whereas the *Nosomma* (two species) is exclusively Oriental (Guglielmone et al., 2014).

The distribution of ticks in the zoogeographical regions is not uniform (Guglielmone et al., 2014). Indeed, some ticks are exclusive to a particular country, or even a particular island. For instance, *Haemaphysalis kadsani* is found in the Australasian Region, but exclusively on Sulawesi Island (Hoogstraal and Wassef, 1977). A valuable dataset of tick distribution in South America containing over 4000 geo-referenced tick records has recently been made available (Estrada-Peña et al., 2019). This database also provided valuable information on the relationship between tick distribution and climate.

Life cycles

The biological cycle of ticks includes phases of egg, larva, nymph (one instar for ixodid ticks and several instars for argasid ticks) and adult (male and female). In nature, the life cycles of various tick species are regulated by seasons and the length of the cycle will depend on several factors such as photoperiodicity, temperature, moisture, and host availability (Olivier, 1989; Apanaskevich and Olivier, 2013). The number of generations per year may also vary widely according to species and geographical region. For instance, the life cycle may be greatly prolonged in harsh arid and cold climates where hosts may be scarce (Olivier, 1989).

Depending on the number of hosts generally used during their life cycle, ixodid ticks can be classified as one-host (e.g., *Rh. microplus* and *Dermacentor nitens*), two-host (e.g., *Rhipicephalus evertsi*) or three-host ticks (e.g., *Am. sculptum*, *Ix. ricinus* and *Rh. sanguineus* s.l.). In the one-host life cycle, all molts (from larva to nymph and from nymph to adult) occur on the host. In the two-host life cycle, one of the molts (from larva to nymph) occurs on the same host and another (from nymph to adult) on a second one. In the three-host life cycle, all molts occur in the environment and all stages feed on three different individual hosts. Some ticks from three hosts may eventually adopt a two-host cycle (e.g., *Am. rotundatum*), depending, for example, on the type of host (Luz et al., 2013). One-host ixodid ticks may complete several generations per year (Borges et al., 2000; Canevari et al., 2017), as may some three-host ixodid ticks in the tropics (Silveira et al., 2009). Nonetheless, it is supposed that one generation a year is likely the usual pattern for most tick species in subtropical and warmer temperate regions (Olivier, 1989).

With rare exceptions, argasid ticks feed on several hosts (multi-host life cycle) and most species have more than one nymphal instar. Molts generally occur in the environment, but a recent finding suggested that *Ornithodoros hasei* may molt from larva to nymph on bats (Muñoz-Leal et al., 2018a). Rare exceptions include *Or. lahorensis* (a two-host argasid tick) and *Otobius megnini* and *Otobius lagophilus* (one-host argasid ticks). Another extraordinary exception is the tick *Ar. transversus*, an exclusive parasite of giant Galapagos tortoises (Hoogstraal and Kohls, 1966). This diminutive tick is a unique species within the order Ixodida: it spends its entire life on its host. It is the only known species of tick whose females lay eggs on their hosts (Hoogstraal et al., 1973).

Seasonality

The seasonal rhythms of ticks in the environment and on the hosts vary widely according to species, developmental stages and geographical region. Tick seasonal patterns are influenced by photoperiodicity and host population dynamics, but also by other factors, such as temperature, precipitation and relative humidity (Olivier, 1989; Vial, 2009; Apanaskevich and Olivier, 2013). These factors will exert different effects on tick seasonal patterns in various species and developmental stages, also depending on

geographical regions (Dantas-Torres et al., 2011, 2019c; Dantas-Torres and Otranto, 2013; Gray et al., 2016). For instance, southern, central and northern European populations of *Ix. ricinus* may exhibit distinct seasonal patterns (Dantas-Torres and Otranto, 2013; Gray et al., 2016). The same seems to be true regarding different *Am. sculptum* populations in southeastern and northeastern Brazil (Dantas-Torres et al., 2019c).

Some tick species have acquired biological and ecological traits that enables a life in a specific type of environment, also during periods of low temperature and low-host density. For instance, some ticks may enter into diapause, a hormonally-controlled arrested development which usually occurs seasonally (Perret et al., 2003; Gray et al., 2016). Indeed, diapause usually occurs before environmental conditions become unfavorable for the ticks, and has a fixed latency period that must be completed before development can resume (Gray et al., 2016). It is mainly regulated by hours of sunlight, which are perceived by bilaterally placed strings of photoreceptors, which are located under the cuticle and the hypodermis of the tick (Perret et al., 2003).

Some ticks can survive underwater for certain periods (Fielden et al., 2011; Giannelli et al., 2012; Sá-Hungaro et al., 2014; Bidder et al., 2019), which may also be an advantageous strategy for ticks living in environments that experience seasonal floods or even for ticks parasitizing hosts which live close contact with the water (Luz et al., 2013, 2020; Dantas-Torres et al., 2019b; Kwak et al., 2020). For example, *Am. rotundatum* is a common parasite of reptiles and amphibians in South America, which means that they may frequently go into the water with their hosts (Luz et al., 2013; Dantas-Torres et al., 2019b). Another example is the sea snake tick *Amblyomma nitidum* that is a specialist parasite of snakes of the genus *Laticauda*, being one of the few ticks that could be regarded as semi-marine (Kwak et al., 2020). Some mammal-associated ixodid ticks may also be more adapted to humid habitats and seasonally flooding soils than others. This appears to be the case of *Amblyomma dubitatum* and *Am. sculptum* (Luz et al., 2020). These ticks parasitize several mammal hosts, but are primarily maintained by capybaras in some regions (Martins et al., 2016; Luz et al., 2020). Capybaras are semiaquatic mammals that uses water bodies to regulate their body temperature, for mating, and to escape from predators. A recent experimental study suggested that *Am. dubitatum* is more adapted to humid habitats and seasonally flooding soils than *Am. sculptum*, which in turn is more adapted to drier habitats than *Am. dubitatum* (Luz et al., 2020). This may partly explain the spatial distribution and abundance of these tick species in different landscapes and seasons.

Prevention and control

The most effective and low-cost way to prevent tick infestations is to avoid tick-infested environments (Dantas-Torres, 2007). Thus, people living in tick-free environments should avoid entering into forested areas, urban parks, grassy picnic areas, or any other environment potentially infested by ticks. For obvious reasons, this is not always a realistic recommendation. In tick-infested areas, sitting on logs, gathering wood, sitting against trees, and walking might increase the risk of tick infestation (Lane et al., 2004). Regardless the primary reason (e.g., working, hunting, walking, jogging and fishing), anyone accessing natural environments are at risk of tick infestations (Fig. 3). As commented above, the tick season vary widely according to species and geographical region. Hence, it is important to consult data from local public health authorities to avoid visiting tick-infested environment during periods of the year when larvae and nymphs are more abundant (Dantas-Torres and Otranto, 2013).

When avoidance of tick-infested environments is not feasible, people entering into risk areas should avoid places potentially infested by ticks, and whenever possible, walk in the center of trails. Wearing light colored clothing makes it easier to find crawling ticks. Likewise, wearing long-sleeve shirts and long trousers and tucking pant bottoms into tops of socks or boots, may also help preventing tick bites. While staying from several hours in risk areas, frequent self-examination and tick removal is important also to reduce the risk of tick-borne pathogen transmission (Dantas-Torres, 2007; Piesman and Eisen, 2008). Children should be checked for ticks more often, paying special attention to the head, neck and ears. Attached ticks can be removed with the aid of fine-tipped

Fig. 3 Fisherman walking through a forested area (A) to access a remote stream for fly fishing (B) in center-west Brazil. In these areas, they are usually exposed to *Amblyomma* spp. ticks, especially nymphs. Photos courtesy of Brenner Ferreira, Tarpon Brazil.

tweezers, by grasping the tick with the tweezers as close as possible to the skin surface, turning it gently, and pulling upward with steady, even pressure. Whenever possible, gloves should be used and tick removal with bare hands should be avoided. Indeed, ticks should not be squeezed, crushed, or punctured, because tick saliva, body fluids, gut contents may contain infectious agents. In areas where different tick species may be found, including vector and non-vector species, it is important to keep the tick in 70% ethanol for future identification and eventually testing for pathogens.

For people visiting tick-infested habitats, commercially available repellents with efficacy against ticks can provide an effective means of personal protection against tick bites (Dantas-Torres, 2007; Benelli et al., 2019). A recent study demonstrated that low concentrations of diethyltoluamide (DEET), picaridin, 2-undecanone, citronellal and nootkatone specifically disrupt the thermal infrared radiation sense of ticks (Carr and Salgado, 2019). There also is ongoing research on novel green repellents based on essential oils (Benelli and Pavela, 2018).

Integrated tick management approaches have also been proposed to control ticks as well as infection by various pathogens in the ticks in natural environments where tick-borne diseases (e.g., Lyme disease) are endemic. For instance, combinations of white-tailed deer reduction, broadcast application of the entomopathogenic fungus *Metarhizium anisopliae* and small rodent-targeted fipronil-based bait boxes have been shown to be an effective to reduce *Ix. scapularis* and infections by various pathogens (e.g. *B. burgdorferi*, *Babesia microti* and *A. phagocytophilum*) in questing nymphs of this tick species (Williams et al., 2018; Little et al., 2020).

Companion animals frequenting tick-infested environments, including dogs and cats, are also at risk of becoming infested by ticks. Therefore, it is important to prevent companion animals from roaming freely in risk areas. If a dog visited a tick infested area, it is important to check the animal for the presence of ticks, which may be difficult to find if small in size (e.g., larvae and nymphs). In any event, controlling tick infestations on dogs is imperative for the wellbeing of dogs themselves, but also from a public health perspective, considering that ticks infesting these animals can also transmit pathogens to humans. Community-based, integrated, tick-management strategies may be effective in controlling ticks on dogs and in the environment, therefore reducing the risk incidence of tick-borne diseases such as Rocky Mountain spotted fever (Drexler et al., 2014).

The best way to keep dogs free of ticks is to apply topical products with repellent activity, such as collars and pipettes containing pyrethroid-based compounds (e.g., permethrin, deltamethrin, and flumethrin), with repel and kill ticks (Otranto et al., 2010, 2017; Dantas-Torres et al., 2013). Repellents cause irritation and toxic effect on ticks, greatly reducing tick feeding (anti-feeding effect) (Otranto et al., 2020). In turn, acaricides do not repel ticks, but kill them soon after they start feeding on a treated host. Chemical groups that possess molecules with killing effect on ticks include, for example, organophosphates (e.g., diazinon and fenthion), formamidines (amitraz), phenylpyrazoles (fipronil and pyriprole) and isoxazolines (e.g., afoxolaner, fluralaner, lotilaner and sarolaner) (Beugnet and Franc, 2012; Rohdich et al., 2014; Six et al., 2016; Cavalleri et al., 2018; Tinkruejeen et al., 2019). Ivermectin is used off-label to control *Rh. sanguineus* s.l. infestations of dogs in numerous countries, including Thailand and Brazil, but is not efficacious (Tinkruejeen et al., 2019). A wide range of formulations (e.g., solutions, shampoos, lotions, sprays, powders, spot-ons, collars and palatable tablets) are available for dogs and eventually cats. It is important to mention that cats are sensitive to several compounds that are safe for dogs. For instance, permethrin is toxic for cats (Beugnet and Franc, 2012). There are, however, specific formulation for cats with other molecules (e.g., flumethrin) that are safe for cats.

Environmental treatment with acaricides may be required in some specific situations, such as in case of high levels of environmental tick infestation in kennels, usually accompanied by high levels of tick infestations on dogs. However, due to the potential negative impacts on nature, environment treatment is not the preferred method for tick control in most of the situations. In addition, the continuous use of acaricides may lead to resistance, representing a major concern in many parts of the world (Villar et al., 2020).

Numerous approaches have been used to control ticks on livestock, including non-chemical and chemical strategies. For instance, non-chemical strategies to control ticks in cattle include the use of tick-resistant breeds of cattle or pasture rotation, which are alternative management practices that may be employed in light infestations, also to reduce the overuse of acaricides (George et al., 2004). Nonetheless, tick control on livestock still largely rely on acaricides. Many products are market to control tick infestations in livestock. These may be an emulsified concentrate, wettable powder or flowable product that can be diluted in water and applied through immersion of animals in a dipping vat, with a hand spray or spray race. Nowadays, products are also available as injectables, pour-on formulations, an intraruminal bolus, acaricide-impregnated ear tags and pheromone/acaricide-impregnated devices. The periodicity of application may vary from region to region and according to tick species (Nava et al., 2019). Nonetheless, the widespread occurrence of resistance to different acaricides has stimulated the search for additional non-chemical alternatives. In this context, anti-tick vaccines have been developed using the midgut glycoprotein Bm86 from *Rh. microplus* as antigen (Rodríguez-Mallon, 2016; Valle and Guerrero, 2018). Vaccination within integrated tick management programs has been shown to be able to reduce the number of acaricidal applications per year that are required to control some strains of *Rh. microplus* in different geographical regions (Rodríguez-Mallon, 2016; Valle and Guerrero, 2018).
